**Speculative Opinion Insufficient Evidence.**—In an action on an accident insurance policy it appeared that the deceased was a locomotive fireman, whose left foot had been injured. Ten days later he returned to work and attempted to fire an engine. He became sick during the run and died a few hours after in the hospital. He had told the nurse he had been drinking ice-water, and had been taken suddenly with cramps and vomiting, but made no reference to his previous injuries. The physician who attended him at the hospital testified that he died of heat exhaustion. The evidence at the third trial of the case was held insufficient to support a verdict for the plaintiff. On the fourth trial new evidence of a medical expert was introduced. This witness had never seen the assured. He was asked a hypothetical question which did not include all the facts as to the assured's symptoms, etc., disclosed by the record. On the fourth appeal it was held that the witness' testimony amounted to no more than the expression of an opinion, in answer to a hypothetical question, not submitting all of the facts, that the assured's death could have resulted from the injuries to his foot, and that the drinking of cold water might have had something to do with it. The opinion was mere speculation and conjecture and insufficient to sustain a verdict for the plaintiff.—Ward v. Ætna Life Ins. Co., Nebraska Supreme Court, 135 N. W., 220.

**Township's Liability for Medical Services.**—Action was brought against a township to recover for professional services in performing a surgical operation upon, and the treatment of, a resident of the township, who had been severely injured by a gunshot, the bone of the right arm being shattered, and the arm near the shoulder being almost completely severed. The evidence showed that the plaintiff treated the patient and met the township supervisor as to payment for the services. The testimony conflicted as to whether the supervisor authorized the plaintiff to treat the case at the expense of the township. Judgment for the defendant was reversed because the trial court erroneously submitted to the jury the question of whether the patient's relatives were in fact poor persons within the meaning of the statute, and authorized them to pass upon that fact. It was held that the supervisor, and not the jury, was charged with the duty of determining whether a poor person was entitled to relief at the expense of the township, and his determination was an official act, which was conclusive on the township in the action.—Belknap v. Township of Benton, Michigan Supreme Court, 135 N. W., 101.

**Limitation of Action for Unskillful Treatment.**—In an action for damages where it is alleged that the defendant, a physician, "undertook the treatment of" the plaintiff, and that "it was the duty of the defendant as physician to properly and skilfully treat the plaintiff, but the defendant did so carelessly, negligently, and unskilfully treat the plaintiff that he was thereby injured," the cause of action is upon an "obligation or liability not founded upon an instrument of writing," and is barred in three years, under subdivision 7, of section 1725 of the Florida General Statutes of 1906.—Palmer v. Jackson, Florida Supreme Court, 57 So., 240.

**Competency as Expert Witness.**—Where a physician has been admitted to testify, and has testified as an expert without objection, a question of his competency as an expert cannot thereafter be raised by a general objection to a particular question.—Patton v. W. M. Ritter Lumber Co., North Carolina Supreme Court, 73 S. E., 167.

CLINICS, DEPARTMENT OF PUBLIC CHARITIES

Calendar February, 1913

MONDAYS

| | | | |
|---|---|---|---|
| *City Hospital* | Surgery | Dr. Dawbarn | 2:30 P.M. |
| *Neurological Hospital* | Neurology | Dr. McPhee | 2:00 P.M. |
| *Cumberland Street Hospital* (Brooklyn) | Surgery | Dr. Pallister | 2:30 P.M. |
| | Oral Surgery | Dr. Shea | 4:30 P.M. |

TUESDAYS

| | | | |
|---|---|---|---|
| *City Hospital* | Dermatology | Dr. Bronson | 2:00 P.M. |
| | Ophthalmology | Dr. Gilfillan | 2:00 P.M. |
| *N. Y. City Children's Hospitals and Schools*, Randall's Island | Orthopedics | Dr. Ogilvy | 10:00 A.M. |
| *Cumberland Street Hospital* (Brooklyn) | Surgery | Dr. Ritch | 2:30 P.M. |
| | Ophthalmology and Otology | Dr. Warner | 3:00 P.M. |
| *Kings County Hospital* (Brooklyn) | Genito-urinary surgery | Drs. Morton and Fraser | 2:00 P.M. |
| | Obstetrics | Dr Commiskey | 10:00 A.M. |
| | Surgery | Dr. Bristow | 2:00 P.M. |
| *Coney Island Hospital* | Medicine | Drs. Nash, Hall, Hegeman and Byington | 3:30 P.M. |
| | Surgery | Drs. Fisk, Bogart, Murphy and Lack | 10:30 A.M. |

WEDNESDAYS

| | | | |
|---|---|---|---|
| *City Hospital* | Genito-urinary surgery | Dr. Greene | 2:00 P.M. |

### CENTENARIANS AND NONAGENARIANS.*

By W. GILMAN THOMPSON, M.D.

NEW YORK.

If one considers the balance of medical literature from the point of view of the age of patients it is very noticeable that with an enormous output of works relating to infancy and childhood the opposite extreme of life has met with comparatively little exact study, even when the disproportionate number of survivors to extreme old age be reckoned with.

In this article it is proposed briefly to review some of the morbid conditions and other phenomena of those who have entered upon the tenth decade of life and to include reference to centenarians. With regard to the latter it is my belief that the number of those in this country who have passed the hundredth year is exceedingly few. It is true that references frequently are made in the public press to deaths at 100 to 103 or more years of age, but they are very apt to be among persons whose exact history is obviously impossible to obtain. For example, a few days ago, the death of an Indian at 131 years of age was recorded, but in such cases tradition and sometimes desire for notoriety may easily be confused with fact, and in several exaggerated statements as to extreme old age I have found upon inquiry that the alleged centenarian must be placed in the nonagenarian decade. A sailor who lately died in a United States naval home was stated in the public press to be 105 years of age. He had been frequently "interviewed," his portrait was published, etc. As I desired to see and study such a case, if authentic, I wrote to the commander of the home, who replied that the naval records showed that the man was 95 years of age at his death and that he had served 50 years in the navy. Like others of his years he found that his age was becoming a topic of general interest and in talking with reporters was accustomed each time to add a year or two to the date of his earliest recollections. The very old have usually survived all who could give corroborative evidence as to their age, their failing memories confuse tradition with fact, and records of vital statistics in this country which are far from perfect to-day are practically worthless if not completely non-existent when sought for in the early dates of the last century. In some few cases among those of English birth or ancestry, and among New Englanders, it is possible to establish definitely a centenarian age limit. I have such a record in a personal ancestor who lived an active life until the age of 102 years, and I possess the photograph of a woman of my acquaintance who lived for six months beyond 100 years. She was a New Englander and the mother of fourteen children, only two of whom survive her. Up to within two weeks of her death her mind was clear, her eyesight was good, and hearing so keen as to be a matter of surprise. She had no special dietetic or other health fads, and finally died from general weakness of the circulation. Her photograph, taken after living 100 years, shows well her remarkable nutrition.

Turning to the mortality statistics of the United States Bureau of the Census it is found that in 1910 in the special registration area, which comprises 58.3 per cent. of the total population of the country, the mortality within the ages under discussion was as follows: 90-94 years, 6,175 deaths; 95-99 years, 1,427 deaths; 100 years and over, 372 deaths. The total deaths for this area were a little more than three-fourths of a million in the same year.

It is interesting to note the principal causes of death at these advanced ages, which were as follows:

| | Years: | | |
|---|---|---|---|
| | 90–94 | 95–99 | 100+ |
| Diseases of the circulatory system | 1165 | 257 | 54 |
| Diseases of the respiratory system | 887 | 197 | 43 |
| Diseases of the digestive system | 354 | 63 | 10 |
| Bright's disease | 314 | 76 | 15 |
| Apoplexy | 485 | 90 | 22 |
| Influenza | 177 | 36 | 9 |
| Cancer | 150 | 22 | 4 |

Under the diseases of the circulatory system, organic disease of the heart is recorded for the three periods above given respectively as follows: 703, 156, 35.

Under diseases of the respiratory system pneumonia ranked as follows: 634, 145, 32, and bronchopneumonia 156, 42, 13. Thus, for the entire tenth decade and also among centenarians these two respiratory diseases taken together rank first as a cause of death, organic heart disease is second, apoplexy third, and Bright's disease fourth.

Among the fatal cases of diseases of the digestive system, enteritis outranks all others by a considerable percentage. There are, however, many cases among the aged of serious intestinal obstruction from constipation. In the census lists above quoted from, there were 25 fatal cases of intestinal obstruction. In my personal observation among the very aged, overeating and consequent overtaxing of the intestine is a very common error. I know a gentleman who shortly after celebrating his centennial died of overindulgence in lobster salad, and I saw a woman of 96 years who died from intestinal obstruction as a result of long-continued overeating, from which her family were unable to restrain her. In her seventh decade she was a moderate eater, but with advancing years her appetite grew and amounted to bulimia. Two sisters were under my

*A paper read before the Practitioners' Society of New York, Dec. 6, 1912.

observation for many years, one died at 92 and the other is at present entering upon her ninety-second year. They were exceedingly fond of what is sometimes called "old-fashioned New England cooking," and sausages, mince pie, doughnuts, green corn and similar heavy articles of diet were among those for which I was not infrequently called upon to administer correctives! An old gentleman of 90, who visited me during the past summer, and who appeared as vigorous as many a man of 70, astonished me by the variety and quantity of food which he disposed of. In such persons the attainment of ripe years appears to be due mainly to the persistence of good digestion, a survival of the fittest stomachs even after other important organs are seriously impaired. As old age advances and activities and diversions become more and more restricted, the appetite often remains undiminished. The limitation of locomotion, the lack of acuteness of sight and hearing, and other weaknesses, may leave the pleasures of the table almost the only gratification in a monotonous existence. In such cases, if digestion remains fairly active, nutrition may be maintained in an astonishing degree. The accompanying photograph of a man of 97 years illustrates well this condition.

Well-nourished man, 97 years of age, with gangrene of the left leg

These patients usually accustom themselves to the nightly use of strong laxative or cathartic pills with which they counteract the effects of excessive eating, improper selection of food and lack of exercise. Sooner or later, however, they are apt to acquire serious, if not fatal, intestinal obstruction.

Quite a different cause for obstruction is found in those of wholly opposite physique, those who are thin and markedly atropic or marasmic. They eat extremely small quantities of food of a type which leaves so little residue that the normal mechanical element of intestinal stimulation is lacking. They become careless about securing proper defecation and often pass several consecutive days without it, until the pain of flatulent distention compels them to seek relief. Through the flaccid abdominal wall, chains of scybalae may be felt, sometimes from the cecum to the sigmoid, and digital examination of the rectum may reveal an enormous mass of impacted feces. In a woman, 92 years of age, I found such a mass, which required removal with finger and scoop through sittings on three successive days before it could all safely be extracted. I would emphasize particularly the importance of rectal examination in the aged whenever serious constipation is present. In another case, the pressure from hardened scybalae above the rectum gave rise to so much congestion as to cause the discharge of considerable blood and mucus. Such cases may only be made worse by the use of cathartics, and oil and subsequent mildly stimulating enemata constitute the proper means of relief. Continued irrigation of the bowel may prove too exhausting in this type of case. A further difficulty arises from the enteroptosis, which often exists in such emaciated patients, and from the colon distention which they often have.

Death from apoplexy is rare among centenarians. It caused only 22 deaths among the 372 cases of 1910. In fact, it becomes progressively rarer after the ninety-fifth year, for the arterial changes which predispose to it are developed, if it all, at an earlier period.

Gangrene of the extremities from obliterating endarteritis or thrombosis is also an infrequent cause of death, but a few fatal cases are recorded. There were 3 among the centenarians and 20 among the 1,427 cases in the second half of the tenth decade. The man, whose good physique is shown in the accompanying photograph, was an Irish laborer, 97 years of age. His age was well authenticated by cross-examination as to dates and corroborative testimony from his family. He had been in excellent health up to the time of his admission to my clinic in Bellevue Hospital to which he applied for a very rapidly progressing senile gangrene of the left leg. He suffered intense pain which was considerably relieved by the method which I have found most useful in the treatment of moist gangrene, the direction of a continuous current of very hot air over the mortifying surface. In a few days, however, he acquired a septic pneumonia to which he naturally succumbed.

Carcinoma, like apoplexy, becomes rapidly less frequent as a cause of death after the ninetieth year, most of the destined victims having died in the sixth up to the ninth decade. In fact, there is a rapid falling off between the eighth and ninth decades, the percentage dropping from 7.8 per cent. in the eighth decade to 2.5 per cent. in the ninth decade, 2.3 in the tenth, and to about one per cent. for centenarians, there having been only 4 deaths from carcinoma among the 372 persons of this lat-

ter class. In the nonagenarian group the chief sites of malignant growth are in the stomach, liver, breast and skin. The bearing of these facts upon the etiology of carcinoma is of interest, for a disease which does not develop until after the ninetieth year may scarcely be due to any hereditary factor, and the infrequency of the disease after this year merely emphasizes the constitutional resistance to extraneous influences which the majority of nonagenarians possess.

Among the diseases of the circulation to which the very aged succumb, cardiac sclerosis and progressive stenosis of the aortic valve would naturally be expected to predominate, and such is the case, but notwithstanding, the nonagenarian is sometimes surprisingly tolerant of the latter lesion. This is no doubt due to the abstinence from all exertion, and a well developed compensatory hypertrophy of the heart which may exist. I have followed several such cases for several years in which there was unexpected absence of the symptoms common to this condition in earlier years, such as vertigo fainting, or any symptoms of failing compensation, like dyspnea, pulmonary congestion or dropsy. Moreover, death is frequently due to causes not immediately associated with the condition of the heart.

Not long ago, I met with a fatal case of typical angina pectoris in a man of 94 years, who had suffered for six months from increasingly frequent attacks, but which did not prevent him from considerable activity, or necessitate his remaining in bed until two days before he died. Among the 1,427 deaths of the census record of 1910 occurring from the 95th to the 100th year, only 3 were due to this cause, and my case was doubtless one of them as it took place in the same year. Among the centenarians there were no deaths from this disease.

It is a present custom to attribute a great variety of ills to arteriosclerosis and high blood pressure, which is doubtless correct, although there is some tendency to exaggeration in this direction. It is, nevertheless, quite noticeable that nonagenarians, whose arteries may have become extremely rigid or markedly thickened with calcareous deposit, frequently do not present any of the symptoms so often explained on this basis in earlier life. They may remain quite free from vertigo, headache, dyspnea, or any serious symptoms of nephritis, and as stated above, angina pectoris and peripheral gangrene are not common phenomena among them. When they do have symptoms of functional character, referable to high blood pressure, it is inexpedient to adopt the more vigorous measures which are used in younger patients. Vasodilators are usually without effect in such advanced conditions, but chloral hydrate in 5 grain doses, despite the prejudice against it as a cardiac depressant is both a safe and often effective remedy, and the bromides and codeine are also beneficial in this type of case.

One meets with a peculiarly fulminating type of pneumonia occasionally in very old persons. The patient, in previous fairly vigorous health, is attacked with sudden severe intrathoracic pain and dyspnea, and almost at once begins to raise typical blood-stained pneumonic sputum, together with a very large quantity of bronchorrheal exudate. In a receptacle the round distinct masses of bright red well-aerated pneumonic sputum float freely in a mass of clear white watery mucus. There are widespread crepitant râles, but pneumonic dullness may be obscured by emphysema. There is no chill, and the body temperature may not rise above 100° or 101° F. The pulse is full, arterial tension is high and cyanosis is extreme. Coma may shortly supervene and the patient may die within 24 hours of the onset of symptoms. I saw such a case not long ago in a man just entering upon his ninetieth year whose condition became very serious within six hours of the invasion. In all such cases, morphine is extremely ill-borne, usually making matters much worse, but moderate doses of codeine may be given with applications to the chest of mustard pastes or poultices to relieve pain. There is nothing like the hypodermatic use of atropine with counterirritation to check the bronchorrhea but cupping may not be satisfactorily performed owing to prominence of the ribs in a thin chest wall. High arterial tension should be reduced, when possible, by chloral or nitroglycerine and catharsis.

This very acute type of pneumonia is in strong contrast with the commoner sort in which the onset is so gradual and physical signs are so indefinite that it may be a day or two before the diagnosis is accurately determinable, although the condition should always be suspected in a nonagenarian who experiences sudden weakness with thoracic oppression. This type of the disease usually demands early and active stimulation of the circulation, for the policy of letting the patient alone in the outdoor air, so often successful in young pneumonia patients is hazardous in the afebrile and adynamic cases among the aged.

The so-called senile epilepsy is more common just before than during the tenth decade, at least as a cause of death. In the census group of 1910 only 4 fatal cases are recorded among the 7,602 nonagenarians, and only one case in a centenarian. When the disease is present, however, the convulsions may become very frequent. I am familiar with a case in a woman of 92 years, who for several years has had convulsive seizures of increasing frequency, until, at the present time, they sometimes number a dozen or fifteen in a day. They are exceedingly rebellious to treatment and in this case codeine and chlorotone proved more effective than the bromides or any other of a long series of sedatives. In the intervals, the patient appears in fair health.

One of the principal difficulties encountered in the treatment of very old patients is that of overcoming their prejudices and obstinacy in matters dietetic and hygienic, for, having lived so long, they naturally believe they know better than anyone else what is best for themselves, and, with a certain irritability, resist interference. They resent the personal contact of the ministrations of a nurse, or refuse to take this or that remedy, so that much tact with firmness may be required in dealing with them. As a rule, also, they are relatively very susceptible to the action of drugs and great care must be exercised not to overdose them. A good general rule is to employ only about two-thirds of the ordinary dosage. A woman of 92 years, whom I had occasion to treat for various ailments, such as chronic bronchitis and attacks of indigestion, would never allow me to see her in bed, no matter how ill she was, for she acquired the notion that if a doctor once caught her there she would never get out of it again, so she would keep me waiting until she dressed and sat up, immediately going back to bed when I had left! A fortnight before her death, however, she gave in, and, for the first time in her life, permitted a nurse to approach

her. Such patients often suffer seriously from lack of attention to personal cleanliness. Originally of cleanly habits, physical or sometimes mental weakness renders them careless and forgetful, with the result that they may acquire considerable cutaneous irritation. In women, I have several times seen ulceration and edema of the vulva extending into the vagina, from lack of cleanliness in micturition, and similar irritation may affect the perineum from carelessness in defecation. Another part of the body which suffers from lack of cleanliness is the mouth, and such teeth as persist become a source of serious irritation. Alveolar pyorrhea, gingivitis and stomatitis are common. From the former, mild grades of septic infection may develop with a subacute temperature and irritation of the heart which may become very irregular in action.

There are a number of diseases common enough in the sixth to the ninth decades of life which are rare among the extremely aged. For example, tuberculosis in the series of the census of 1910 caused only 26 deaths in the first half of the 10th decade, 5 in the second half, and none among centenarians. In these periods biliary calculi are only recorded 5 times in fatal cases, all being before the 95th year. Prostatic enlargement, although common and troublesome, was a cause of death only 35 times in the first half decade, 12 times in the second, and was not reported among centenarians.

One would suppose that having braved the vicissitudes of life for 100 years one would be content quickly to await the end, but in 1910 one suicide was recorded in a centenarian and nine among nonagenarians. It is not stated, however, in how many of these cases there might have been melancholia or other mental aberration.

There are many modern theories to explain extreme longevity on the basis of individual peculiarities, from the intestinal chronic toxemia idea of Metchnikoff to the functionless ductless gland idea of Lorand ("Das Altern"), particularly of thyroid failure, but no one theory appears applicable to a majority of cases. In many persons the attainment of nonagenarian age appears to be due chiefly to favorable environment, and freedom from harassing worries and poverty. They are like Bill Nye's yellow dog, of whom he was accustomed to assert that "the only real joy that animal had in life was *not* being kicked." They have not been buffeted by the world's cares and trials, and are blessed with serenity of mind and uniformity of function. On the other hand, longevity is about equally found among the struggling poor. The long-lived Bulgarian peasants from whom Metchnikoff derives much of his argument in favor of the use of sour milk are of this type, and among the Irish and Scotch are found many instances of extreme longevity in the laboring classes. The Irishman 97 years of age, above referred to, certainly did not owe his years to ease of life, for he had been a hardworking day laborer almost up to his tenth decade.

A majority of nonagenarians give a history of long-lived ancestry, and there are many families remarkable for this characteristic, but it is not an essential one, by any means, for a line of such ancestry may be broken by intervention of infectious diseases or by the unhygienic or irrational habits of individuals.

All things considered, however, heredity appears to be a much stronger factor in producing nonagenarians than any special habits, as of diet or hygiene, for the latter are found to present the greatest variety in different cases—hence extreme longevity is largely a matter of natural selection.

That the aged very often exhibit no predominating symptoms of any one disease to which their death is attributable, is a striking fact. They may become so universally sclerosed and atrophic that a general weakness is their only complaint, and although they may have marked arteriosclerosis, nephritis, or myocardial change, the more active symptoms which characterize such diseases early in life may be entirely wanting. They rarely show marked edema, for example, and the typical picture of the last stages of failing compensation of the heart, so familiar in early life, the orthopnea, cyanosis, and general anasarca, etc., is very rarely met with. They die suddenly and peacefully—it is as if the clock had run down. Hence in the mortality statistics "senility" is so often given as the cause of death and accepted by the health authorities without further question.

In the group of cases in 1910 this was the final diagnosis in 26 per cent. of the nonagenarians and in 40 per cent. of the centenarians. Fortunate it is, indeed, that the reward of a long life well spent should so often be a peaceful ending without the long drawn out sufferings so common in the middle decades.

34 East Thirty-first Street.

## THE PRESENT STATUS AND FUTURE SCOPE OF THORACIC SURGERY.

By DE WITT STETTEN, M.D.,

NEW YORK.

ASSISTANT VISITING SURGEON TO THE GERMAN HOSPITAL; INSTRUCTOR IN CLINICAL SURGERY IN COLUMBIA UNIVERSITY.

Though no branch of surgery has undergone a more remarkable development and been the subject of more active discussion within the memory of even the latest generation of surgeons than the modern surgery of the thorax, though the literature teems with descriptions of apparatuses for entering the chest cavity and of technical operative details based mainly upon experimental data, there has been a peculiar dearth of papers dealing with the more practical phases of the situation. With the exception of here and there an isolated case report, very little effort has been made to enlighten the profession generally on the present status and future scope of thoracic surgery as far as its practical application in the treatment of pathological conditions of the chest is concerned. The writer had the good fortune to be present in Breslau eight years ago at the actual birth of this latest member of the surgical family, and he has since watched the growth of that lusty infant to promising adolescence with the liveliest interest. He will attempt to present here a compilation of the situation today. If what follows has a somewhat pessimistic ring, this must not be interpreted as a lack of enthusiasm for the future of thoracic surgery when it reaches maturity, but rather as the justifiable scientific scepticism of an impartial critic.

As is well known, the modern conception of intrathoracic surgery dates its origin to Sauerbruch's brief communication in the *Zentralblatt für Chirurgie* in the early part of 1904. In this article he showed that it was possible to exclude the harmful effects of pneumothorax in operations upon the chest—the *bête noire* of the thoracic surgeon—by

the use of a negative pressure chamber surrounding the operative field. Up to this time, notwithstanding the high standard of excellence of general surgery and the perfection of aseptic measures, the chest was practically a *noli me tangere* to even the most daring surgeon. To be sure, an occasional attempt had been made to perform intrathoracic operations with the aid of the Fell-O'Dwyer or other methods of artificial respiration or with Murphy's pneumopexy, but altogether it was a highly unsatisfactory and dangerous procedure. In fact, nothing noteworthy had been accomplished except the extrapleural operations on the heart and pericardium for wounds and suppurative pericarditis and the costal resection or simple thoracotomy for empyema. When Sauerbruch's original paper and his further more elaborate contributions on the same subject appeared it was truly as if a bombshell had exploded in the surgical camp. Immediately on all sides modifications of and improvements on Sauerbruch's method sprang up and great were the hopes expressed as to what the future would bring. The main bone of contention was as to the preference of the method to be used for preventing surgical pneumothorax. Brauer and Petersen, hot upon Sauerbruch's trail, claimed that the method of positive pressure was simpler, cheaper, and more practical in every way than Sauerbruch's cumbersome, expensive, and nonportable negative pressure chamber. This particular controversy has been carried down to the present day, but a new factor was added in 1909, when Meltzer and Auer suggested the now well-known principle of continuous intratracheal insufflation as cheaper, simpler, safer, and more satisfactory in every respect than either of the two previous methods. I do not propose to enter upon a protracted discourse as to the relative merits of these three well-known methods. I have had the opportunity of observing the working of all three types of apparatus, and I offer herewith a summary of my personal conclusions.

As to the relative value of minus and plus pressure, whether we use the simple negative pressure chamber of Sauerbruch or the ingenious combined negative and positive pressure cabinet of Willy Meyer on the one hand, or the positive pressure apparatuses of Brauer, Robinson, Green and Janeway, Kuhn, or Tiegel, etc., on the other, one fact has been fairly definitely established by Dreyer and Spannaus. In 1908 these two, working in Kuettner's clinic, proved rather conclusively that physiologically these two methods are practically identical, both producing a higher pressure in the interior of the lung than on its surface, thus preventing its collapse. To be sure, Tiegel has very recently shown that the blood pressure in the endothoracic veins and pulmonary artery rises a trifle more under positive pressure, thus throwing more work on the right ventricle, but this seems to be of no great consequence. In favor of the negative pressure method it may be said that the management of the anesthesia is more satisfactory, particularly when the patient vomits or is otherwise troublesome, and further, that there is less danger of aspiration. In favor of the positive pressure method the arguments of simplicity, comparative inexpensiveness, and portability of the apparatus can be advanced.

The Meltzer-Auer method has certain features which commend it in preference to either of the two former. The apparatus is cheaper by far, and much more portable. With it operations can be performed anywhere and practically under any conditions. The patient may be easily placed in any position to suit the operator's convenience. The anesthesia is exceptionally well under the control of the manipulator of the apparatus. When the chest is opened there is almost a complete apnea, which is particularly advantageous, as respiratory movements are a great annoyance to the surgeon working in the thoracic cavity, where often the greatest delicacy of manipulation is imperative. Further the question of respiration can be practically ignored. There is no necessity for the patient to breathe, and as long as the heart action is satisfactory one need not worry about respiratory failure, so easily possible in these operations on and around such vital organs as are contained in the chest. The apparatus really does the breathing for the patient. With either of the two older methods, should respiratory failure occur, a dilemma arises that is not easily overcome. On the other hand, the intubation is frequently a rather difficult and lengthy procedure, and it is not quite certain yet that the danger of pneumonia from the irritating effects of the concentrated anesthetic coming into such direct contact with the pulmonary alveoli is not considerably greater than with the other procedures. Eisberg, Fisher, Robinson, and others have made decided improvements upon Meltzer's primitive, experimental apparatus to overcome these difficulties and to successfully apply the is profuse expectoration, as in bronchiectatic cavities, insufflation is not to be recommended. Negative pressure would there be the method of choice, as it would permit freer expectoration. One decided advantage of either the negative or positive pressure cabinet over the insufflation method is that it may be used in the after treatment of the case to keep the lung distended and to facilitate drainage, as Willy Meyer has recently pointed out. Repeated intubations would be most objectionable. Further, the negative or positive pressure chamber may be used with local anesthesia, which is out of the question with the insufflation method. As will be seen, each method has certain features in its favor, and, like methods of anesthesia, no one can be considered the most desirable. The one best suited to the case should be selected.

Whichever method we choose to use, one fact is certain. The bugbear of surgical pneumothorax no longer exists. The thoracic cavity can be entered surgically with almost the same impunity as the abdomen. I use the word "almost" advisedly, for the convalescence of thoracotomy cases is not quite as uneventful as that of the average laparotomy case. The shock to the patient is certainly greater. Frequently a pleuritic exudate develops and the pleura is undoubtedly much more susceptible to infection than the peritoneum. Further, the possibility of a postoperative pneumonia is decidedly greater. However, these dangers can be coped with, and I have little doubt that soon they will play an unimportant and minor rôle.

Coincident with the development of measures to eliminate the dangers of surgical pneumothorax, great strides have been made in certain diagnostic fields. I refer to the progress in esophagoscopy, bronchoscopy, and radiography. The details of this progress are well known to all, and I merely mention it in passing, for it has contributed not a little in bringing thoracic surgery to its present position, and it will be of the utmost importance in advancing it still further.

Granted, now, that we are able to make a more accurate and earlier diagnosis of the various forms

of thoracic disease; granted, also, that we may safely open the thorax, what can be done when we have entered the thoracic cavity? Are the hopes that the future of thoracic surgery will rival the brilliant present of the surgery of the abdomen justified? I have decided that the best way to answer these questions is to discuss seriatim the various pathological conditions of the chest which have been, which can be, which might be, and which might not be amenable to surgical interference.

Let us begin with the chest wall. Without question, large primary tumors, sarcomata, chrondromata, and osteomata of the thoracic wall can be much more radically extirpated now that the danger of pneumothorax is obviated. This statement in a measure applies also to the secondary involvement of the chest wall in mammary cancer, either from the primary tumor or from the recurrence. Sauerbruch, Kuettner, and others have successfully resected the chest wall when involved by beast carcinoma. So far as the large primary tumors of the chest wall are concerned, they are a great rarity and they are likely to become still more uncommon as the public becomes more enlightened. The utility of resection of the chest on account of its involvement in mammary carcinoma is open to serious question, for the presumption of internal metastases when this stage has been reached amounts to almost a moral certainty. Advanced costal tuberculosis with the extension to the parietal pleura now offers a more grateful field for radical surgical intervention, and injuries to the intercostal vessels can be most successfully attacked. Exploratory thoracotomy can be performed to establish a diagnosis of intrathoracic disease. It is an operation entirely analogous to the laparotomy performed for exploratory purposes, but it must be always understood that as yet it is by no means so devoid of danger. While in the present state of our knowledge there may be some justice in a more or less indiscriminate use of this procedure merely for the purpose of establishing intrathoracic surgery on a firmer basis, I believe that eventually there will be no indication for the operation unless there exists a reasonable hope beforehand that something can be accomplished after the chest cavity has been entered.

The lungs and pleura require our next consideration. The severer injuries or ruptures of the lung with progressive hemorrhage, socalled "tension pneumothorax" and mediastinal emphysema, demand thoracotomy and pulmonary suture, though differential pressure or insufflation is by no means a necessity, as the lung is already collapsed and the chest cavity has adjusted itself to these changed conditions. Sauerbruch claims, however, that the operation is more satisfactorily performed under these measures. If the above mentioned threatening features do not exist, it is the consensus of opinion that palliative therapy is the most satisfactory. Pneumonotomy might be indicated to extract a foreign body from a smaller bronchus, inaccessable to the bronchoscope. However, this would be a most unusual indication, as foreign bodies almost invariably travel no further than the main bronchi, from which they can usually be extracted by means of the instrument,

The acute abscess of the lung offers an especially satisfactory field for the application of the newer methods of intrathoracic surgery. If possible, the operation should be done in two stages, the affected lobe being first sewed into the thoracotomy wound and then incised after adhesions have formed, and the rest of the pleural cavity has been walled off. What has just been said in regard to the acute abscess applies with equal force to gangrene of the lung. For the chronic pulmonary abscess conditions are not as satisfactory, owing to the denseness of the abscess wall. Besides the above described incision in two stages, extensive rib resection is likewise necessary to mobilize the chest wall. If, in these suppurative or gangrenous affections of the lung, a large pleural exudate exists or the diseased lobe is adherent to the chest wall, differential pressure or insufflation is, of course, superfluous. An isolated bronchiectasis is likewise an indication for pneumonotomy, and frequently, also, for a thoracoplasty. When there are multiple bronchiectases, which is usually the case, they should not be attacked in the direct fashion. I shall refer to this phase of the subject again when I speak of the surgical treatment of pulmonary tuberculosis. After an incision of a bronchiectatic cavity, a bronchial fistula is very likely to develop. This condition is very resistant to surgical treatment. Pneumonectomy or resection of the affected lobe or a part thereof might be attempted, but this is as yet an extremely dangerous procedure. While simple and successful in the animal experiment, resection of the lung has proved fatal in a large percentage of cases in the human being, though Sauerbach, Kuettner, and Robinson report successes.

Pneumonectomy might likewise be indicated in cases of primary malignant neoplasm of the lung or pleura, in secondary involvement of the lung and pleura from tumors of the chest, in ecchinococcus of the lung, and in localized actinomycosis, and this operation has even been suggested in localized tuberculosis. Tumors, to be sure, are usually inoperable when diagnosed, though the *x*-ray and exploratory thoracotomy may bring them more within the sphere of surgery. The medical treatment of actinomycosis has been fairly satisfactory and will probably become more so in the future, while few surgeons take the suggestion of excising a tuberculous lobe seriously. Axhausen reports a successful operation for ecchinococcus of the lung. An ingenious proposition has been made by Bruns and Sauerbruch to produce atrophy and cicatrization of the lung in multiple bronchiectases and tuberculosis. They suggest ligation of the branches of the pulmonary artery. Though Sauerbruch has seen improvement follow this procedure in two cases of bronchiectasis, the operation is still in the experimental stage.

Although not directly dependent upon the differential pressure or insufflation methods, there has developed within the past decade a tendency to treat two diseases of the lungs hitherto belonging to the domain of medicine by surgical measures. I refer to emphysema and tuberculosis. As far back as 1859 W. A. Freund suggested that emphysema was due to a primary, rigid dilatation of the thorax. Upon this theory he has proposed the extrapleural resection of the costal cartilages on both sides to mobilize and narrow the chest wall. The operation has been performed many times and does seem to be of value. Its exact mode of action has not yet been satisfactorily explained. The selection of the cases is very important, the operation is not devoid of danger, and even after temporary improvement the symptoms have reappeared with an increase in their severity. Various surgical measures have been suggested in the treatment of pulmonary tuberculosis. The production of an artificial pneumothorax by

nitrogen, as proposed by Murphy and Forlanini, has been practised in cases where no pleural adhesions exist, and where the disease is unilateral. Many have reported good results with this procedure. Freund has advanced the theory that the frequency of apical tuberculosis is due to a narrowing and immobility of the upper aperture of the thorax on account of a primary shortening of the first costal cartilage. He has proposed an extrapleural chrondectomy of the first costal cartilage to correct this error of development in cases of incipient apical tuberculosis. Kausch and Seidel have had successful results.

A much more radical plan of treatment of tuberculosis of the lung has been developed by Friedrich, following a suggestion of Brauer. He calls the operation "total thoractoplastic pleuropneumolysis." This operation is based really upon the same principle as the induction of an artificial pneumothorax, namely, the production of cicatrization of the diseased lung by compression. The operation is nothing but a more or less extensive extrapleural rib resection and a deossification and mobilization of the chest wall, producing an extrapleural pneumothorax. It is really only applicable in a unilateral affection. It may also be used in multiple bronchiectases. A pad is used during the after treatment to exert pressure on the chest wall. Friedrich and others report satisfactory results, though the operation is by no means free from danger. In a modified form the operation may be applied to the upper lobe alone, the first three or four ribs being resected—socalled apicolysis. In many of these cases local regional anesthesia may be used.

I have already referred to ligation of branches of the pulmonary artery and to pneumonectomy in tuberculosis. As to the utility of surgery in pulmonary tuberculosis, I think we can sum up the situation in a very few words. There may be an occasional instance in which an otherwise healthy patient has a severe but localized pulmonary lesion, say an isolated cavity. Such a case might possibly warrant surgical interference, perhaps a costal pleuropneumolysis of Friedrich. In general, however, hygienic, climatic, and vaccine therapy are so much more rational, have been so successful, and give promise of still further success that I am confident that surgery will always play a very negligible rôle in the treatment of this disease.

Before we leave the lungs and pleura, one word on the subject of empyema. Have these newer methods improved our treatment of this condition? Personally, I do not believe that much advance has been made. I am firmly convinced that the use of differential pressure or insufflation is directly contraindicated in empyema operations, unless the case is clearly of an interlobular form, when it should be treated like a pulmonary abscess. Especially do I believe that these various pressure methods are injurious in the metapneumonic type of the disease, for they can only tend to create further disturbances in the already diseased lung. In localized empyema the use of these methods will only tend to diffuse the pus. The after treatment is not shortened, as some had hoped. I can see no object whatsoever in using these methods, as the lung is already collapsed and the chest cavity has adapted itself to these changed conditions. Aspiration and the injection of antiseptics, for example, formalin, in empyema, I regard as dangerous, unscientific, and unsatisfactory except in the most exceptional cases. Suction drainage after operation has some decided advantages. I must not omit the mention of Beck's bismuth paste in chronic sinuses. This has undoubtedly saved many a patient from an extensive decortication and thoracoplasty. Ochsner is particularly enthusiastic over the use of bismuth paste. The ever present danger of bismuth poisoning must not be disregarded, and too large quantities, too concentrated paste, and too frequent injections should be avoided.

We now come to the surgery of the heart and great vessels. It is claimed that the various pressure methods are a great aid in the suture of the heart wounds, especially inasmuch as 80 per cent. of all heart wounds are complicated by injuries of the left pleural cavity. One can certainly operate on the heart with greater impunity and rapidity if one need not worry about opening the chest cavities. I favor the use of differential pressure or insufflation in these cases though the results in extrapleural operations have been very gratifying. Peck in a recent analysis of 160 cases found 36 per cent. recoveries, with more than 60 per cent. of the fatal cases succumbing to secondary causes, usually infection. As to the actual diseases of the heart, the only one in which operative intervention has been dreamed of has been mitral stenosis. Some years ago Lauder Brunton suggested an incision of the mitral valve to relieve extreme grades of this condition. Cushing, Branch, and others have tested this possibility experimentally, and seem to think well of it. I greatly doubt, however, its adaptability to the human subject. In the first place, the condition of the patients is invariably so unfavorable that any thought of a severe operative procedure is entirely out of the question, and, even if it were not, we could only succeed in converting the stenosis into the very little better insufficiency. Further, a heart adjusted for a stenosis is not at all suited to accommodate a sudden regurgitation, and even should this be possible, when the incision in the valve cicatrizes the stenosis would recur.

No noteworthy change has taken place in the treatment of suppurative pericarditis. A very good suggestion was, however, made by Brauer in 1902 in the treatment of adhesive pericarditis, where, owing to the immobility of the heart on account of its fixation to the chest, marked circulatory disturbances occur. His plan is simply an extrapleural resection of the bony part of the chest wall over the cardiac region, several ribs, and, if necessary, a part or the whole of the sternum being removed, thus giving the heart action freer play. This mobilization of the precordium he calls "cardiolysis." The condition necessitating this operation is rare, but a number of very successful results after this procedure have been reported, notably by Petersen and Simon, V. Beck, Danielsen and Fritz Koenig. Curtillet and Péllissier report a successful case in which the pericarditis was of tuberculous origin.

Injuries to the great vessels are usually rapidly fatal, though if very promptly attended to they may be operated on successfully. Von Eiselsberg has sutured with success a stab wound of the root of the pulmonary vein, and Kuettner has done the same with a wound of the pulmonary artery. Heile has recently ligated successfully the pulmonary vein of the left lower lobe on account of a bullet wound. Injuries to the aorta and its branches, to the venæ cavæ and innominate veins are easily accessible by transpleural routes. Aneurysms of the branches of the aorta may become more amenable to surgical treatment, for proximal ligation is certainly a simpler procedure today than it ever has

been. Recently Lusk has revived interest in the wiring of aortic aneurysm, though it is very questionable if this procedure will ever attain great popularity.

Within the past few years a number of extremely interesting suggestions, based upon experimental work, have been made in regard to the surgery of the great vessels, which I shall now briefly consider. In 1907 Trendelenburg, after numerous successful animal experiments, suggested the extraction of the embolus after embolism of the pulmonary artery, unfortunately a not altogether infrequent postoperative complication in surgery. I shall not enter into the technical details of the operation, which are most ingeniously conceived. The operation has been attempted a number of times on the human with invariably fatal outcome as yet, though a patient of Krueger lived five days and succumbed eventually to a secondary pneumonia. I cannot see that the operation has much justification. Small emboli are by no means invariably fatal, while under the most favorable conditions the operation itself is a most serious menace to life. As a matter of fact, the operation would only be indicated in extreme cases where exitus occurs almost immediately after the lodgment of the embolus. In such a case it would be almost impossible to even get the patient on the table alive, much less off of it. Even if it should be possible to successfully extract an embolus, another is unlikely to follow or a thrombus is likely to form at the original site. Trendelenburg claims that there is a group of cases in which the obstruction is not complete at first, and that the patient may live from ten to sixty minutes after the lodgment of the embolus. Acocrding to him, this type offers the indication for operative interference. Personally, I would rather prefer giving the patient the chance of getting over the condition without operation, though a patient may yet be saved by operative intervention who would otherwise have perished. The operation is done extrapleurally, although the pleural cavity may easily be opened, and then some form of pressure apparatus would be useful.

The marvelous experimental work of Carrel on the great vessels is doubtless well known to all. Nothing but admiration is due the ingenuity and untiring effort of that brilliant experimenter, and from the purely scientific, physiological standpoint his remarkable results are of the greatest significance. From the practical point of view, however, I feel that they will help us but little. In aortic aneurism or coronary disease the condition of the patient is usually such that any thought of a serious operative procedure is out of the question, and the fact that a healthy dog will tolerate an aortic resection or a coronary anastomosis is no argument that a diseased human will. Further, the local conditions are so different that absolutely no analogy can be drawn between the surgical work which has been done on the sound, normal vessels of the dog and that proposed for the diseased, sclerotic and calcareous structures in the patient. You may be able to suture successfully the elastic artery of an animal. I am certain that, even if the patient stood the shock of the operation, you would not succeed with a suture of the friable walls of a diseased aorta. The suggestion of Munro to ligate the patent ductus arteriosus will scarcely receive practical application, as this anomaly gives slight symptoms and offers an excellent prognosis.

The extension of the surgery of the intrathoracic portion of the esophagus has really been the main aim of all the workers in this field. Notwithstanding the most earnest endeavor of numerous surgeons, in spite of really brilliant experimental successes, little has been accomplished practically. Wounds or rupture of this organ in its course in the thorax might be sutured with success. Foreign bodies may be extracted by transpleural operation, but this should only be undertaken if they are inaccessible to competent esophagoscopy, or if they are impacted and cannot be dislodged without the danger of seriously injuring the organ. Benign strictures would only come into consideration for operation if they are impassable. For this condition Fischer has proposed a transpleural cardiotomy and retrograde bougieing. I think that an abdominal gastrotomy might accomplish the same object with less risk to the patient. If the stricture is confined to the lower portion of the esophagus, an esophagogastrostomy—an anastomosis between the esophagus and stomach in the thorax might be considered. Cardiospasm with fusiform dilatation of the esophagus is usually amenable to dilatation with the cardiodilators of Gottstein, Plummer, or Einhorn. Willy Meyer's longitudinal esophagoplication with vagolysis might occasionally be indicated to reduce an unusually large pouch. Intrathoracic diverticula warranting operations are rare. Should one exist it may be excised or an anastomosis could be made between the sac and the stomach according to Lotheissen's suggestion.

The radical cure of esophageal cancer has been the Holy Grail of the thoracic surgeon. Three years ago Sauerbruch collected all the cases in which the attempt at radical excision had been made, and found 20 cases with 100 per cent mortality. Since then many other attempts have been made, but they have uniformly failed, although cases have lived as long as two weeks after operation. I had hoped, eight years ago, when I assisted Sauerbruch in his early experiments and saw the astonishing results of esophagectomy in dogs, that within a very short time the radical cure of cancer of the esophagus would be an established fact. This type of carcinoma is relatively benign, it metastasizes slowly, and prompt diagnosis is usually possible, as early symptoms are the rule. This latter statement is especially true since esophagoscopy and radiography have reached their present perfection. I have become less optimistic, however, in the course of the past years. The esophagus lacks a peritoneal coat and cannot be sutured like the intestine. It is composed of soft muscular tissue and can stand no tension whatever. The carcinoma, even in the early stages, extends for some distance along the tube, and frequently the vagi are involved in the growth. Technical difficulties are nearly insurmountable in most instances, and insufficiency of the suture line, infection, or pneumonia are almost certain sequelæ. I am very much inclined to agree with Sauerbruch that only those cases are really operable in which a small tumor exists at or near the cardiac end. Then a resection may be performed and an esophagogastrostomy done after pulling a part of the stomach into the chest through the diaphragm. If the tumor is higher up a resection may still be possible, but then both ends of the gullet must be closed, as an anastomosis between the two ends is out of the question and an esophagogastrostomy can no longer be done. A gastrostomy, with or without an esophagostomy in the neck, is, of course, needed. The esophagus in

the neck might be eventually connected with the stomach by means of a jejunal loop as proposed by Wullstein and Roux, or by a skin tube, or by both, but these operations border on the fantastic, though Lexer last year actually reported a case in which total esophagoplasty had been successfully performed in this way on account of an impassable cicatricial stenosis. Very recently Jianu, on the basis of animal experimentation, has proposed the excellent plan of forming a new esophagus out of the greater curvature of the stomach. Roepke has performed this operation with success on the human subject. An exploratory thoracotomy is especially indicated in suspected esophageal cancer, and only through its aid will the operable cases be found and will anything be accomplished.

A word on the surgery of the mediastinum. From its anterior portion intrathoracic goiter, enlarged thymus glands, tumors developing from thymus rests or lymph glands—sarcomata, endotheliomata, dermoids—might be removed. Olivier has recently collected the thymectomies from the literature and has found 23 cures in 42 cases. Charles H. Mayo added another successful case a short time ago. Von Eiselsberg has successfully extirpated a dermoid, and Friedrich a so-called "Askanazy glandular tumor" from the anterior mediastinum. The incision and drainage of mediastinal abscesses or broken down glands might also be considered. The intrathoracic portions of the thoracic duct and the pneumogastric and phrenic nerves have not as yet been brought within the domain of surgery.

So far as the diaphragm is concerned, I confidently believe that the treatment of lacerations of the diaphragm and diaphragmatic herniæ will be greatly simplified, now that these can be attacked transpleurally without difficulty. In combined thoracic and abdominal injuries, for example a lung and liver wound, transpleural laparotomy should be the method of choice. Sauerbruch has had two successful cases treated by this plan. For infections of the liver and the subphrenic space the old method of thoracotomy, then stitching the diaphragm to the parietal pleura, and finally incising extrapleurally has not been improved upon.

This finishes a summary that I have tried to make both complete and accurate. I have purposely omitted all but the most passing references to technical details; I have avoided a discussion of incisions, drainage questions and the new instrumental armamentarium that has grown about this branch of surgery, as their consideration is of too special interest and would be out of place here. It is difficult to prophesy as to what the future will bring, but I feel that it will take many years of toil for thoracic surgery to attain the pinnacle that abdominal surgery has reached to-day. Perhaps it will never be attained. The organs of the thorax are of a different character than the abdominal viscera—they are of a more vital importance, physiologically, and of a more delicate mechanism. Then mechanical conditions are vastly more unsatisfactory. Beyond the shadow of a doubt great progress will be made, but from the very nature of things the possibilities of thoracic surgery will always be somewhat restricted. Nevertheless, as I have shown, much has already been accomplished in a comparatively short time, and much more will still be done. It is the duty of all of us to face the problems yet to be solved, not to be discouraged, nor deterred from further attempts by one, or even repeated failures, and to work with all our energies in striving to bring the surgical treatment of the diseases and injuries of the thorax to the highest possible state of perfection.

## PUBLIC PROTECTION AGAINST MENTAL DEFECTIVES IN PARIS.

### THE WORKING OF THE SPECIAL INFIRMARY CONNECTED WITH THE POLICE DEPARTMENT.

By E. CASTELLI, M.D.,

NEW YORK.

CONSULTING PHYSICIAN TO THE COLUMBUS HOSPITAL; ATTENDING NEUROLOGIST TO THE POST-GRADUATE SCHOOL; VISITING NEUROLOGIST TO THE NEUROLOGICAL HOSPITAL.

The Depot Special Infirmary of Paris is, in my estimation, the organization which solves, in the most practical and satisfactory manner, the problems of public protection against the unbalanced elements of society left at large principally because neither the medical profession nor the police authorities and the public have found the formula authorizing them to seclude the unbalanced and criminal-to-be, in order to take care of his condition, to guarantee him, and society as well, against the dangerous reaction of insanity. Paris, through the organization of her infirmary, and by allowing the people at large to be the judges of danger and to be in a very easy way in touch with the organization, has reduced to a minimum the number of crimes and suicides filling her chronicles every year. We must not forget that criminality is a contagion and that many times a wave of crime or suicide strikes a populated center simply because a few have started the example.

The subject necessarily involves us in many details of a dry and uninteresting nature which we must remark and study to appreciate fully the entire results obtained.

The special infirmary of the Depot has been organized to receive all patients afflicted with mental troubles who might be dangerous either to themselves or to the general public. When the doctor of the special infirmary has ascertained that an individual behaving in an extraordinary manner is ill, he sends him to the Clinical Asylum (also called Ste. Anne's Asylum). The depot infirmary is thus only a temporary resting place for patients, who as a rule make but very short stay there, since the authentication of mental troubles is sufficient to have them transferred to Ste. Anne's Asylum.

There occurs, however, some rare cases in which the special infirmary doctor thinks it advisable to keep the patient for a few days, either because he needs supplementary information on the circumstances which led to detention, or suspecting a simulation he wishes to be quite certain that the mental trouble is in reality existent. It is not necessary that all individuals suffering from mental derangement should pass through the special infirmary. For instance, take the three following examples of cases affected by trouble in connection with the domain of psychiatry.

1. When the family or friends notice a marked change in the character, intelligence, habits, or general behavior of a relative or friend, they can have him conveyed to the Clinical Asylum, where one of them has to sign the demand for admission and produce at the same time a certificate from a doctor who has examined the patient and concluded that he should be placed in a lunatic asylum. This is called voluntary confinement.

2. If a patient undergoing any kind of treatment in hospital shows symptoms of mental trouble, the head physician of the hospital makes out a certificate stating the condition of the mind of the patient and the necessity for his admission into a clinical asylum. The chief of the police of the district where the hospital is situated comes then, takes the case under his charge and proceeds with the formalities for his confinement.

3. Anyone creating a disturbance, either at his abode or in the street, and becoming a danger to himself or the public, may be sent to the depot special infirmary, in order to be examined by the doctor.

Of these three cases only the last has to deal with the special infirmary, but it is necessary to bring them into notice in order to show that it is only under certain circumstances that lunatics pass through the special infirmary.

We shall now study the organization of the depot special infirmary, and in order to facilitate this, we shall consider the patient before entering, then we will examine his sojourn there, and see what he has become on leaving it. Finally, we shall consider the transformations and improvements which could be brought about in the working of this establishment.

We shall then have to examine successively: (1) How and under what circumstances a patient is brought into the depot special infirmary. (2) The routine, the conditions of living, and the examination of the patient in this infirmary. (3) What becomes of the patients when leaving the special infirmary. (4) What are the alterations, transforma-

tions, or modifications that would be desirable for the improvement in its organization.

1. There are two conditions under which a patient afflicted with mental trouble can be taken into the depot special infirmary.

First.—A patient on whom a special examination has been made by the police officer, and whom it has been judged advisable to put under observation. This is the most frequent case.

Second.—A patient under treatment in an establishment belonging to the district of the Seine (such as hospital, workhouse, homes, etc.) showing signs of mental trouble during his residence. In these cases, as we shall see later, the doctor in attendance makes out a certificate which enables the police officer to send to the special infirmary. This case is much more rare, and we omitted to mention it in our introduction in order to simplify our subject.

Let us now consider each of these two cases.

1. In the case in which the police officer has made an examination. If the patient is dangerous to himself or to the public security, the police officer is notified. (*a*) If it happens in the patient's own house, then the parents, the neighbors, or the concierge go and inform the police officer. (*b*) If it happens in the public street, the policeman takes the patient to the police station in order to cause no more disturbance and to give the offender the necessary help.

In any case the police officer must make out the following report:

Police Office Dept.
District of the Seine
Ward
Office of District Police
5th division
5th office
.....Section
.....
Official Report concerning the person demented
.....
Urgent
For the Special Infirmary.

FRENCH REPUBLIC.

In the year Nineteen hundred.....
We.....
Police officer especially in charge of the district.... legal police officer auxiliary of the Attorney of the Republic....According to the article..... law of June the 30th, 1838, and the instructions of the circular of the Prefect of Police.
Etc., etc.....

In this official report the police officer gives particulars of his visit and the circumstances which led to it (complaints, letters, report of the police, etc.) then he states his inquiry on the spot, his examination, the statements and evidence received from the neighbors and family and from the concierge, then concludes with the necessity for having the patient taken to the special infirmary of the depot, that he may receive the requisite attentions. He dates his official report, signs it, and has it signed also by the people who gave evidence in his inquiry and the patient is then usually sent to the special infirmary, but not always, and for two reasons: (1) Physical condition of the lunatic may be bad, or (2) physical condition of the lunatic is satisfactory.

Bad Physical Condition of the Lunatic.—If it is a question either of organic injuries due to the progress of the mental illness itself, or of injuries that are self-inflicted (attempts at suicide by firearms, knife, drowning, poison, asphyxiation, jumping out of window, run over, self-mutilation, etc.) there is urgent necessity of giving medical or surgical help to the patient and this predominates over that required by the mental troubles. Under the conditions the police officer sends the patient directly to the hospital and when the more serious injuries have been attended to, then the head doctor makes out a certificate for sending the patient to the Clinical Asylum.

Satisfactory Physical Condition of the Lunatic.—When the police officer has finished his inquiry and written out his official report, he calls on the patient or sends for him to come to his office under some plausible pretext. Whatever may have been the means employed to secure the lunatic, he is conveyed by carriage to the depot special infirmary, accompanied by two inspectors of the police in civil clothes, furnished with the report of the police officer. The lunatic is immediately admitted into the infirmary on presentation of the document; then he is searched, deprived of any object which would be prejudicial to his security such as braces, necktie, handkerchief, belt, etc. We shall see later what becomes of the patient after admission into the special infirmary.

2. The case of a patient under cure in a provincial home. As we said before, the patients cured in ordinary general hospitals are not sent to the special infirmary when they give signs of unsound mind, but they are sent straight to the Clinical Asylum. However, when a patient is cured in a provincial home (such as Nanterre, Villers-Coterets, etc.) that is to say, out of Paris, it is managed in the following way: After the report of the head doctor stating the mental unsoundness and necessity of treatment in a special establishment, the police officer or the mayor of the town makes an inquiry on the spot, draws up a report, and sends the patient to the Special Infirmary or to the Clinical Asylum. In the end the method is the same as that for patients in hospitals, but while hospital patients in Paris are sent straight to the Clinical Asylum, those of the Provincial Homes are sent either to the Special Infirmary or to the Clinical Asylum.

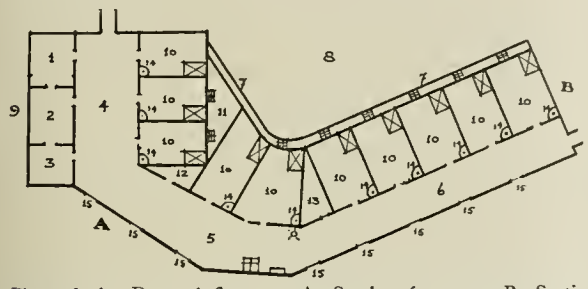
Having now seen how and under what circumstances the lunatic is sent to the Special Infirmary of the depot, we will proceed to investigate his sojourn in this infirmary.

*The Daily Life and the Examination of the Lunatic in the Special Infirmary of the Depot.*—As soon as the lunatic is admitted to the Depot Special Infirmary he is under the authority of the doctor and of the police. If the doctor recognizes the pathological character of the insanity which caused the arrest of the individual, he draws up a report in consequence of which the Prefect of Police takes the necessary measures for the admission of the patient to a lunatic asylum. If, on the contrary, it is a case of an individual who has simulated mental aberration to escape the tribunal, the doctor declares that there is not mental trouble and the culprit is sent to the depot to be brought to trial.

*Infirmary of the Depot; Arrangement of the Building and Rooms.*—In this connection we shall consider: (*a*) The building, the examination room for the patient, and cells. (*b*) The communication of the Special Infirmary with the outside and with other parts of the building. (*c*) Sleeping and feeding of the patients.

Building, Examination Rooms, Cells.—The depot special infirmary is situated in a part of the Prefecture of Police, a basement of the exterior court yard opposite the entrance at 3 Quai de l'Horloge. The building is of no architectural value and presents a sad and gloomy aspect, and being surrounded by the high walls of the other parts of the Palace of Justice, it gets but very little air and light; it is formed of two long corridors joining each other at right angles in front of the entrance. On entering there is on the right a corridor from which open a certain number of cells, destined for the men, and

those reserved for the women. In front is another corridor, on the right of which there are a series of cells for men and the left in succession, the room where archives are kept in which are registered the admission of all persons who have passed through the special infirmary, the doctor's room and the manager's office, the interne (assistant) guardian room is on the first floor. In order to give an idea of the arrangement of the building we have made out a plan which is not of absolute exactitude with regard to dimensions, but which will give a better idea than any written description.



Plan of the Depot Infirmary.—A, Section for men; B, Section for women; 1, Entrance office; 2, Doctors' office; 3, Records; 4, Corridor leading to depot; 5, Vestibule; 6, Corridor leading to section for women; 7, Fore-court; 8, Detention Courts; 9, Attendants' hall, 2nd floor; 10, Cells; 11, Court; 12, Storeroom; 13, Storeroom; 14, Water Closets; 15, Windows.

*Examination Room.*—The examination room in which the doctor visits the patients and makes out the certificates is of a rectangular form, and is rather large, as it has to accommodate, besides the doctors and their medical staff, certain other persons admitted to follow the consultations for the purpose of medical study and practice. This room contains everything that can possibly be required in a psychiatric examination.

*Cells.*—The cells are rectangular rooms, about 5 meters long, 3 large and 4 high. The cubic air contents is about 55 to 60 cubic meters. Each cell is lighted by a barred window with a penthouse outside and guillotine blind; they cannot be opened without the help of the overseer. These windows look out on a covered way which separates them from the prisoners' court where the vagabonds and other persons are kept, who are undergoing punishment or waiting for trial.

The cells contain no other furniture than a bed fixed into the wall with legs cemented into the floor. On the bed there is a rye straw mattress, a bolster of oats, and a sheet folded in two, all covered with a gray blanket like those used by soldiers. In a corner of the cell, near the door, there is a water-closet with automatic valve and provided with hydraulic ventilation for driving away ammoniacal emanations. In the summer chlorine is put in the basin. The walls are bare and painted a yellowish gray. The light is feeble, giving an impression of demi-obscurity.

Some of the cells are for raging lunatics. Then the walls are padded all around to the height of about 2 meters. In other respects there is nothing special in the arrangement and furnishing of these cells.

The Communication of the Special Infirmary with the Outside and with the Other Buildings.—As it is easy to see by the plan the special infirmary is in free communication with the outside world, that is to say, that anyone who wants to enter it for any reason has only to cross the gate of the Quai de l'Horloge and present himself at the infirmary. It is therefore easy to take there a patient who may be suspicious or one whose health would not suffer many comings and goings. Moreover access to the infirmary is facilitated for all daily service of the staff in attendance. The special infirmary communicates with the other buildings by means of the doors at the ends of the corridors. These doors enable persons showing mental trouble to be brought to the depot or those having simulated madness to be sent away from it after medical examinations, thus simplifying the removal of patients from one service to another and preventing useless journeys.

Sleeping and Feeding of Patients.—We spoke about the bedding when describing the cells. If the patient is capable he is obliged to make his bed, but if not, the ward nurse is obliged to clean the cell and make the bed. The food is very simple. At 9 o'clock in the morning the patient gets a loaf of bread (about 800 gr.) which has to last him for the whole day, and some soup; this soup, which is given through the wicket, is served in an enameled iron bowl the spoon is wooden; no glass, plate, fork, knife, or other article whatever is allowed. The patient can eat on his bed or standing up. At half past four they have again soup and a piece of meat weighing about 80 gr. Prisoners for trial have meat only twice a week, Thursday and Sunday, but the lunatics, although they have the same food as the prisoners, benefit by the daily meat diet. Moreover, the doctor can permit the patient's family to send him a more abundant and healthy food. The patient is also allowed, if he has the means, to have his meal brought in; of course, wines and spirits are expressly prohibited; water or tisane to drink are provided.

*Medical Staff.*—The medical staff is composed of a head doctor, an assistant doctor, a second assistant doctor to take the place of either of the other doctors when on leave or obligatory absence, two house doctors, these belonging to the lunatic asylum of the Department of the Seine they assure the medical service day and night, serving alternately; they have to examine and take notes on each new case brought in and make their report to the doctor on service either that day or the day after.

*Administration Staff.*—The administrative service of the depot special infirmary is in two parts. One is for the special care of the lunatic, and resides in the infirmary itself; the other looks after the administration and judicial position of the lunatic and resides in the office of the Prefecture of Police. The staff which has to deal with the lunatic is composed of four men and five women assistants. They must be of good morality and enough experience to be able to look after them properly. The staff which has to deal with the administrative and judicial situation of the lunatic has nothing to do with the patients. They have only to receive and put together all the official reports of the police officers and the medical certificates, together with orders of arrest, based on them and given by the Prefect of Police. It is a purely administrative work having nothing to do with the care given to the patients. This staff constitutes the fifth bureau of the first division.

*The Stay of the Patient in the Special Infirmary.*—Arrival of the patient at the infirmary.—The patients arriving from the police offices and brought to the special infirmary are put into the hands of the *overseer* who, after having read the official report, makes the patients undress, examines them very carefully, and writes on a special book if they find any ecchymoses, wounds, or any other sign of traumatism on their skin. Their clothes are

searched to ascertain if they have any weapons, either offensive or defensive, hidden about them, their jewels taken away and deposited in the clerk's office, and lastly they take away from their clothes everything that could be used for making straps, cords, etc., which might be employed for committing suicide either by hanging or strangling.

Then the patient is dressed again in his own clothes and taken to the cell which he is to occupy. From this moment all his movements will be watched, his abnormal actions, his delirium, his agitation, his sleeplessness are registered in order that the doctor may know exactly the state and the reactions of the patient in his new situation. If his agitation is very intense then the straightjacket is used in order to prevent the organic exhaustion produced by his unregular, incessant movements, and also to prevent him from voluntarily or involuntarily wounding himself. Sometimes it is necessary to tie the patient to his bed to keep him lying down. Lastly in urgent cases the assistant on duty can administer a chloral or give him an injection of morphine.

The patient is almost always alone in his cell, although constantly watched through a wicket in the door, by the attendant; the wicket remains closed when the patient does not require constant supervision.

Patients are admitted at any time of the day, but as a rule they are sent in about 5 P.M. from the police station. For instance, if a drunkard is arrested for causing disturbance in the street he is kept at the police station until he gets sober, but at 5 o'clock, if he is delirious or talks incoherently, he is sent to the special infirmary. It is very seldom that two or three patients are put together in the same cell, then only for want of room, but if this should be necessary it is done on the doctor's advice only and the patients chosen are only those who are calm.

*Visiting and Examination of the Patient.*—Patients are examined twice a day, viz., at 11 A.M. and at 3 P.M. A list of the names of the newcomers is presented to the doctor on his arrival; also a registered report on each of them. Previous search has been made in the archives of the infirmary to ascertain if the patient has ever been brought in before and if so, how often. In the later case the reports on this patient are sent for from the fifth Bureau of the Prefecture of Police. All these documents are submitted to the doctor who finds in them necessary and valuable information for helping him to make out his certificate. It happens that patients are brought in without having been identified by the Commissary of Police through having been struck with amnesia and therefore lost all remembrance of their name and address.

These patients are temporarily classified as "unknown" and their photograph is joined to each of their reports until their identification. The patient is taken to the doctor's office by one or two of the wardens of the infirmary and they assist the patients during their examination and interrogation.

The doctor's examination may present three different cases: 1. The case of individuals having lawsuits, simulating madness in order to avoid prison. If this is found out the doctor makes a special report and the individual is transferred to prison. 2. The case of individuals having had slight passing mental troubles, drunken, epilepsy, etc., which have left no consequences behind, and who have perfectly recovered the normal sense at the moment of their examination. Under these circumstances the doctor can follow one of the three following courses:

(*a*) If the individual can prove his means of earning a livelihood and has committed no crime he is set free at once without any other formality than the medical certificate.

(*b*) If the individual has only had a passing mental attack and is a pauper, the doctor proposes his admission to the Provincial Home at Nanterre, making the demand at the Third Bureau. This is a humanitarian measure for putting the patient out of danger of misery and want and sparing him from law proceedings which might be taken against him for vagrancy or horseplay while under the influence of drink.

(*c*) If at the examination the patient is no longer suffering from mental trouble, but has committed an offense while not in the full possession of his intellectual faculties, he is set free under the threat of law proceedings which may be taken against him for damage which he may have done to certain persons.

When the doctor has to deal with a lunatic two courses are open: (*a*) A patient may show mental trouble, on the nature of which the doctor cannot form a decided opinion; he will then keep him for several days under observation in the special infirmary for reexamination; thus it sometimes happens that a patient has to be kept several days at the special infirmary for the doctor to be absolutely sure about his case.

(*b*) When the psychiatric diagnosis is evident the doctor immediately makes out his certificate and the lunatic ward at the Prefecture of Police sends the patient to the asylum. Of course the doctor of the infirmary has at his disposal every means of clinical investigation which can help him to form his diagnosis as rapidly as possible.

(*c*) Drawing up of the certificate. The doctor's certificates are simply medical aand treat only of the mental troubles of the patient, while the official report of the Commissary of Police treats of the danger that the patient may be to himself and to his neighbors. When the diagnosis is certain the doctor states it, giving the enumeration of the principal symptoms and mentioning at the same time any physical troubles. When the diagnosis is uncertain the doctor gives only a description of the principal symptoms and the medical legal reactions shown by the patient before his entrance or during his stay in the infirmary.

(*d*) Duplicate of the certificate. This expression signifies the order of confinement given by the Prefect of Police, which is based on the certificate made out by the doctor of the depot special infirmary. The medical certificate is given to the infirmary to be copied and entered in the register.

There are two kinds of duplicates. The first is the confinement by order of a lunatic who has been sent to the depot special infirmary in consequence of a report made by the Commissary of Police; this is the most usual as it concerns almost all lunatics.

The second is the confinement by order of a lunatic in hospital or in prison and showing mental trouble. These two duplicates are shown on the following page. They are taken to the Prefecture of Police 5th, First Division, there they are signed by the chief of the office in the name of the Prefect of Police and brought back to the special infirmary, where they will accompany the patients until they leave the infirmary.

*Division of Patients when Leaving the Depot Special Infirmary.*—After the medical examination and the consequent administrative formalities, the situation of the patient is arranged in the following way: (*a*) If it is a case of madness he is sent to a special establishment. (*b*) If it is a case of transient mental trouble he is set free. (*c*) If it is a case of simulation he is either set free or sent to prison, according to circumstances.

Let us examine in detail these three cases:

If it is a madman two courses are possible. When the patient is poor he is sent to Ste. Anne Clinical Asylum. As the infirmary doctor has examined these patients either in the morning or in the afternoon and sent them away in the evening, their stay in the infirmary is consequently for a few hours. Exception, however, is made for doubtful cases, simulated cases, or second offenses, which require a longer time for observation, but in no case are they kept for more than two or three days. Patients are transferred to Ste. Anne between 7 and 8 o'clock P.M. The administration looks after the transport. The conveyance is divided into eight compartments 1 m. 40 in. height, 0/60 wide and 0, 80 centimeters deep, lined with leather on three sides. The fourth side is a looking-glass covered with a solid wire netting to prevent the patient from breaking it. There is a fixed seat for the patient to sit on and owing to the low height he could not stand. Patients are locked into these cells by a safety lock and two bolts and carried in this way to the clinical asylum under the responsible care of the transport warder. Once admitted into Ste. Anne they have no longer anything to do with the depot special infirmary, but are in the keeping of lunatic asylum and the Prefecture of Police.

In the case of a well-to-do patient the family can ask permission of the doctor of the special infirmary to send the patient to a private hospital, which is always granted. The certificate of the infirmary doctor is sent to the Prefecture of Police, who has the man transferred to the place chosen by the family. Although in a private hospital the patient is always under the superintendence of the police and cannot get out without their consent. The transfer of the patient from the infirmary to the private home is always made by the administration and under its responsibility. If no demand has been made by the family the well-off patient is sent to the common asylum, although all his expenses are claimed from his family.

*Transient Mental Derangement.*—In this case the patient is set free after having received the necessary care, but it may happen that, owing to his mental state the patient may have lost his means of livelihood and then he is sent to the Departmental Home at Nanterre, where he is provided with work. When he has gathered together a little money he can leave the house and try his chance of having work outside.

*Cases of Simulated Madness.*—If it is found out that the individual tried to be put in confinement in order to get a shelter from starvation, he is severely reprimanded and then set free. If, on the contrary, an individual arrested for whatever reason has tried to simulate madness in order to avoid the punishment of his fault, he is sent to the depot; two things may happen: The individual has simulated mental trouble after his arrest. In this case he is sent back to the depot or prison where he was awaiting trial and the law proceedings continue against him. The individual simulates mental trou-

bles after having committed a crime outside. He is examined by special infirmary doctor, convicted of simulation, and transferred to the depot.

*Conclusion.*—From the study of all this we may conclude that the working of the special infirmary of the Prefecture of Police is good. Its manner of carrying out the work may seem complicated at first sight, but its regularity is, nevertheless, simplified by the fact that all these various formalities are executed almost automatically. The institution and the organization of this infirmary facilitate the prompt admission to it of all dangerous people on account of mental derangement; its proximity to the depot facilities, the transfer to that building of simulators, and of all those under police investigation, who, during their detention have shown mental troubles. The only points it would be desirable of bringing to a state of greater perfection concern rather the daily working of the infirmary than the institution itself. It would be a great advantage if these old buildings could be better ventilated and that the hygienic rules for the patients should be more strict. In few words: Better ventilation, more hygiene, more cleanliness, and better food. With the exception of these small details and speaking generally we are right in saying that the work of the depot special infirmary is good and its institutions supply a real need in a large city like Paris.

## HODGKIN'S DISEASE.*

By JAMES DUDLEY MORGAN, A.B., M.D.,

WASHINGTON, D. C.

ATTENDING PHYSICIAN, GARFIELD MEMORIAL HOSPITAL.

When there are painless progressive lymphatic enlargements in many parts of the body, often with enlargements of the spleen and sometimes of the liver, with the blood showing no marked alteration, save more or less anemia, we call the affection Hodgkin's disease.

Glandular swellings in various parts of the body had long been noted by clinicians but to Hodgkin, the pathologist of Guy's Hospital, who in 1832 published in the "Transactions of the Royal Medical and Chirurgical Society" a series of cases of enlargement of the lymphatic glands and spleen, do we owe the first accurate clinical description of this disease; but it was not generally accepted as an entity until Wilks, in 1865, described a number of cases and spoke of the affection as Hodgkin's disease. Virchow, Cohnheim, and later Billroth and Trousseau had written of the similarity of the disease to leukemia, even before the announcement of Wilks, and pointed out the essential factors of difference. Even as early as 1828 Craigie described the nature of the glandular change. It was Bonfils of France and Wilks of England in 1856, who, being unaware of the researches of Hodgkin in 1832, published simultaneously and independently a series of cases similar to those described by Hodgkin; and Wilks, then connected with Guy's Hospital, exhibited unknowingly with his own cases specimens from Guy's museum which he later found had been collected by Hodgkin.

*Etiology.*—The factor causing Hodgkin's disease is for all purposes of a clear conception, as much unknown to-day as in the time of Hodgkin. It is seen and accepted that certain conditions and diseases seem to predispose strongly toward the development of the lymphatic enlargements. Some of the patients who have developed Hodgkin's disease, had recently had some acute infectious disease, as measles or scarlet fever, or had suffered much with tonsillitis or nasopharyngeal catarrh.

The disease is much more common in the male than in the female, the proportion being as three or four to one; it occurs more in the young, the age ten to thirty covering most of the cases; those under ten years would represent, according to Longscope, one-fifth of the cases; it is found in all countries and in all climates, but seldom develops in the negro.

*Morbid Anatomy.*—A definite picture can be given of the morbid processes of the disease and although the growth may take on a different appearance and morphologically undergo changes from a secondary infection, still the early reticular changes in the endothelium of the gland, with its distinct capsulation and its always lymphadenoid character, and if metastatic, of glandular growth, keep it within a correlation which entitles it to a description of its own.

*Blood changes* are not many or marked. There is generally an anemia, which is represented in a decrease in the red corpuscular count; the hemoglobin falls, and in the later stages there may be some polynuclear leucocytosis.

*Symptoms.*—The disease as a rule begins with very slight manifestations of any kind. What brings the case under observation is generally the enlarged masses situated on one or both sides of the neck, oftenest in the cervical region, and with these enlargements there may or may not be some ill health; the patient may complain of fatigue, fever and general malaise.

On examination, nodular growths are found on the side of the neck, in the axillary and inguinal regions and in the breasts of the female; the spleen, liver, kidneys and thyroid may be enlarged, and later progress of the disease may indicate the involvement of the retroperitoneal and the mediastinal glands. The pressure from the nodular growths leads to much disfigurement, great embarrassment in breathing, difficulty in hearing and swallowing, bronzing of the skin and neuralgic pains, all incident to an encroachment by the extensive hyperplasia of the lymphoid tissue. The patient becomes progressively anemic, develops fever, sometimes jaundice, and ascites; the dyspnea often becomes very marked and exhausting, and the patient steadily and surely fails.

*Case History.*—B. M., aged 48, Russian, married, had measles and smallpox; up to 21 had good health; then had much gastric and intestinal trouble with vomiting and after some months was treated for tapeworm, of which she was relieved. Between the ages 24 and 41 had nine children and four miscarriages. Menstruation at 14 and ceased at 46. Has suffered for past four years with pains in joints and complains of ear, nose and throat troubles. Is constipated and has palpitation of the heart, and says she has lost weight and is very weak. Her mother is living and is in good health—aged 68; her father died at 63. The glandular enlargements have been present since seven years and have been increasing more the last year.

The pulse is 90, temperature, 98.7 deg.; the patient seems older than her years, is anemic, restless,

*Read before the Medical and Surgical Society of Washington, D. C., December 5, 1912.

continually snorting and clearing her throat; is somewhat deaf and her throat shows partial occlusion of nasopharynx and obliteration of left palatine arch; a swelling the size of large pear is seen beneath and extending backward and downward from the left ear toward the thyroid and thymus glands; it is very tense in portions and has lines of partition; there is another swelling, the size of a walnut, under and back of the right ear; there is a small nodule in the right breast and a movable mass, the size of the kidney, to the right of the umbilicus; the inguinal glands are also enlarged. In her chest and heart nothing of importance is discovered; the liver and spleen are not enlarged. A radiograph shows a tumor mass in the right abdomen, but the shadow cast is not sufficient to be outlined. Uranalysis is negative; Wassermann reaction, single positive; tuberculin reaction, negative; leucocytes, 8.950; differential count: lymphocytes 14, large mononuclear 18, polymorphonuclear 68; erythrocytes, 4,840,000; hemoglobin, 85 per cent.

The *prognosis* is most unfavorable. The glandular swellings may remain stationary for years and then, for some unknown reason often following tonsillitis or some infection, may suddenly and rapidly enlarge.

Hodgkin's Disease.

The *diagnosis* is often difficult unless a complete history of the case is known and a blood examination with a histological examination of the tissue growth is made. Longscope, Simmons, and others have confirmed the findings of Dorothy Reed and placed Hodgkin's disease on a definite histological basis. Reed has shown the proliferation of the endothelial cells and excess of lymphocytes filling the lymph sinuses and later excess of fibrous tissue.

Lymphosarcoma, tuberculosis, syphilis, lymphatic leukemia are often confusing, unless every point is weighed in considering our diagnosis. The course of lymphosarcoma is more rapid and more painful, tends to involve surrounding tissues and to have metastases; the glands show infiltrating fat lobules with numerous round cells, and there is a lymphocytosis in the blood. Splenic anemia is like Hodgkin's disease only in the enlarged spleen and the few blood changes. There is a constant tendency to hemorrhage, especially gastrointestinal, and the lymph glands are never enlarged. On the examination of the blood would rest principally the diagnosis of lymphatic leukemia; in both we may have enlargement of the spleen and lymphatics, but the spleen in leukemia is much larger, and there is a well marked leucocytosis. Tuberculous glands are generally submaxillary, and do not as frequently involve both sides of the neck; they have, as does lymphosarcoma, more tendency to break down and ulcerate; if physical signs are lacking, tuberculin should be tried, or a section of one of the glands made, which would show minute tubercles. The course of syphilitic glands is not so protracted; they have a tendency to grow smaller, and treatment would establish the diagnosis; a Wassermann or luetin test could be made.

*Treatment.*—Permanent improvement, either from surgery or medicine cannot be looked for. The complete removal of the glands or their enucleation is invariably followed by recurrence, either at the former site or in some other region. The giving of arsenic in gradually increasing doses, as recommended by Nélaton and endorsed in the writings of Billroth, is still the practice of to-day, and is one of the very few remedies showing any actual benefit. The *x*-rays should always be tried, as they reduce the swelling and retard new developments; unfortunately on cessation of the treatment the growths recur and treatment has to be again instituted.

919 McPherson Square.

## SCARLET FEVER; IS THE DESQUAMATORY STAGE CONTAGIOUS?

By FRANCIS H. MEAD, M.D., M.R.C.S., Eng.

SAN DIEGO, CALIF.

About two years ago I was asked to look over the children in one of the public schools in the city of San Diego for a suspected case of scarlet fever. There were a few cases in the city at the time and public attention had been called to the matter. I found a little girl, the child of Christian Scientist parents, in the acute stage of primary desquamation, in which stage she had been at school for five days. I took her to her home and interviewed the parents. No physician had previously seen the child. She had had a fine scarlet rash some two weeks previously and a sore throat and the parents "thought she had possibly had scarlet fever." The schoolroom was carefully fumigated, her desk treated, her books and school paraphernalia removed and burnt. I expected an outbreak among the pupils of the school. Not a single case developed.

A year later I found a Mexican child in another school in almost similar conditions. She had been kept at home for the sore throat and rash, sent to school without any physician having seen her when the desquamation was beginning. Similar precautions were taken. Again, not a single case developed.

It is, of course, out of one's power to experiment with cases, but I subsequently allowed a child under my care to circulate freely among the members of his family, many of whom were children, while in the primary desquamating stage, and to go out, greatly to the indignation of his neighbors. He was not allowed to come in direct contact with other children outside, as far as I am aware. There was no further infection in the home or outside.

There is no doubt that of recent years opinions of the infectiousness of the desquamative stage of

scarlet fever have been undergoing a change. In the article on Scarlet Fever, by Dr. J. H. McCollom in Osler's second volume, there are the following remarks: "The length of time that a patient ill with scarlet fever should be isolated has been the subject of careful study. Some physicians go so far as to say that the desquamation is not infectious, but that the contagium of scarlet fever is in the discharge from the mucous membranes. This is a little too radical an opinion, and is not in accordance with clinical experience. There is no doubt that during the active stage of primary desquamation scarlet fever is infectious. There is very grave doubt if the secondary desquamation is infectious." The English statistics subsequently given in the same article report that in 204 cases of discharge from hospital with "peeling without complication," only two gave return cases. This is an extraordinarily small percentage; 2.7 per cent. of return cases from desquamation is the highest which the English observer, Dr. Simpson, can attain.

To quote from Dr. Chapin's extremely interesting recent work on "The Sources and Modes of Infection": "Most of the disease in other families develops within a few days of the primary case, and is doubtless due to contact infection before the disease is recognized. Between the end of the second week and the termination of the isolation the disease extends to other families in the house in only 0.6 per cent. of the cases, and in most of these it is known that *isolation is not carried out*, and that there is free intercourse between the families." My experience with the cases cited, which exhibited no other lesions except the desquamation when I found them, bears out Chapin's subsequent remark.

"In Providence scarlet fever cases are usually sent home from the hospital in four or five weeks if free from nose and ear discharge. No regard need be paid to desquamation as the experience of English hospitals has shown that no danger is to be feared from that source."

As a means of consulting the highest authority we have on contagious diseases, I laid the subject before the surgeon-general of the U. S. Marine-Hospital Service. The following reply was sent me: "This bureau has no knowledge of any experiments establishing in a definitive manner the contagiousness or non-contagiousness of the scales of desquamation present in cases of scarlet fever. A review of the literature seems to reveal a tendency towards considering them as innocuous. In the absence of definite information on the subject there is a reluctance on the part of health officers to abandon the old quarantine methods based on the disappearance of desquamation. The following statements taken from recent writers may prove of interest: 'It appears from our present knowledge that scarlet fever is a disease that is transmitted by contact and not by fomites; that the scales of desquamation play very little, if any part, in the transmission of contagion, the chief danger lying in the buccal, nasal, and aural secretions; and that the release of each case should be decided upon its merits.' Curtis, p. 428, *Journal, American Public Health Association,* June, 1911.

" 'At present there is a tendency to believe that the scales do not possess great power of transmitting the disease during all stages of desquamation, and especially toward the termination of that process. On the other hand, it has not been proved that the scales are innocuous, or that they become so at any period of the stage of desquamation. Consequently it becomes of great importance to control the dissemination of these scales.'—p. 668, *Journal, American Medical Association,* March 4, 1911.

" 'I am free to confess that I believe in the contagiousness of scarlet fever by means of desquamation, although I consider this source far less dangerous than the discharge from the nose, throat, and ear, or the acute skin eruption. . . . And if the scales themselves do not contain the offending agent, who can vouch in any given case that they have not been contaminated by the virulent and tenacious "germs" containing the discharge from the mouth, nose, and ears?'—Sobel, p. 657, *New York Medical Journal,* October 1, 1910.

" 'The consensus of opinion now is that the exanthem and exfoliation are due to a toxin and that the unfoliated epidermis is probably not infectious. In English hospitals, by paying attention to the care of the mucous surfaces and neglecting the desquamation, the percentage of return cases was reduced from 4.27 per cent. in 1902 to 2.15 per cent. in 1903. The period of detention was shortened from 48 to 34 days.'—Schauman, p. 1338, *New York Medical Journal,* June 25, 1910.

" 'While we have no definite knowledge, so far as bacteriology is concerned, regarding the infectiousness of the desquamative stage, there is abundant clinical proof that the epidemic scales have the power of communicating disease.'—p. 360, Vol. II, Osler's Modern Medicine.

" 'The doubt as to the contagiousness of desquamating epithelium is becoming more generally entertained. Scarlet fever is not only contagious before desquamation begins, but not infrequently after it has completely terminated. It is obvious, therefore, that the infection must reside somewhere in the body apart from the cutaneous surface.'—p. 356, Welch & Schamberg's Acute Contagious Diseases.

"It is hoped that this information may prove satisfactory."

To summarize my own opinion on the matter statistics show that only in a very small percentage of cases, secondary cases of scarlet fever arise from exposure to desquamation. Only a comparatively infinitesimal number of cases thus exposed catch the disease. Where the very few cases have developed from desquamation it is probable that the desquamation was infected from discharges from the nose, throat, or ears. We have not an official statement of quarantine for various diseases. The old-fashioned quarantine for scarlet fever, however, should go, and with no nasal, aural, or buccal complications, and no kidney involvement the time of quarantine for an ordinary case will be cut down to 28 or 30 days.

Union Building.

## THE ASSOCIATED OUT-PATIENTS CLINICS OF THE CITY OF NEW YORK—A SOCIAL FORCE.

By E. H. LEWINSKI-CORWIN, Ph.D.,

NEW YORK.

Ours is the age of getting together and of team work. Great combines of all descriptions, trusts, syndicates, pools, gentlemen's agreements, trade and labor unions, farmers' associations, consumers' leagues, city, State, national, and international soci-

eties, bear sufficient testimony to the fact that the trend of modern life is toward integration and concentration. It is a process of evolution, in the Spencerian sense, and of simple evolution at that, for the intensity of the forces which produce it is so great as to prohibit much differentiation of the resultant aggregate. Hence, justifiable fear of it lest it destroy independence and individual initiative, the precious products of competition.

This fear may also be the reason why two phases of our social life, higher education and charity, drag so far behind the general movement towards combination or cooperation. Personal equation; philanthropic pride; personal, sectional, denominational, religious, or racial ambitions are probably contributory causes of no mean importance.

Of all forms of charity, medical charity seems to be in the most rampant individualistic state. The individualism of philanthropists is in this instance strengthened by the rivalries of the members of the medical fraternity and the medical schools. The existing competition among the hospitals, although wasteful at times, undoubtedly had many beneficent results, absolutely non-existent in the case of dispensaries, which are regarded as step children of the hospitals or to borrow a phrase from the industrial world, as by-products of much inferior value.

*Lack of Recognition of Dispensary Possibilities.*—The dispensary is almost invariably looked upon by the Boards of Managers as the Cinderella of the hospital household. It is rarely well equipped and never cared for very properly and always expected to be self-supporting. Recently one of the hospitals of the city pointed out with pride that its dispensary is not only self-supporting but has made so many thousands of dollars of profit for the hospital. Why such an attitude should prevail it is hard to understand. Obviously not much faith is placed in the efficacy of medical treatment at the dispensary and no recognition is made of the great possibilities of the dispensary in preventive medicine and in public health movement.

*The Dispensary Shortcomings.*—As a consequence low standards of therapeutics and administration were allowed to prevail with great harm to all concerned; the indigent sick, the physicians and public welfare.

The abuse of the dispensary by those who by reason of their economic status are not entitled to gratuitous treatment is an evil of long standing. In December, 1877, the New York State Board of Charities appointed a special committee "to consider and report upon the best means of preventing these abuses."[1] The Committee reported the next year, recommending that a close attention to the rule of geographical limits is most necessary and that it is desirable that the several dispensaries should act in harmony and that by "occasional conferences many of the minor abuses to which medical charities are peculiarly exposed would be most conveniently remedied."

Present conditions are not very different from those of 1877, despite the fact that since 1899 we have on our statute books a law which makes false representation by dispensary applicants a misdemeanor punishable by fine, and in the opinion of the State Board of Charities the law has already accomplished almost all that can be expected of it in this matter. As a result of this as well as the fact that the dispensary clientèle is drawn from all over town the overcrowding in most of the dispensaries is rendering efficient treatment impossible. In a neurological clinic of one of the dispensaries it was figured out that, granting that all of the physicians were on duty for fully two hours daily, that no time was lost, whatsoever, that no two physicians attended one case at the same time, etc., the amount of time given to each patient, under these ideal conditions, was a little over one minute. There is no need to speak of the value of medical work to the patient and to the average physician under such circumstances. If it be added that modern scientific equipment is lacking in very many of the dispensaries and that the physicians are unpaid in a majority of them; that social investigation and follow-up work are almost untried because of its great cost under the present system, or rather lack of any system; that home visiting is practiced on a small scale; we will have a faint picture of the dispensary problem, which urgently calls for an immediate and satisfactory solution and is equally pressing in this city as in every other large city of the country.

The Chicago Medical Society, in a special report issued November, 1910, states the problem in the following series of questions:

"Are the sick poor obtaining really efficient service? Is the system accomplishing its purpose?

"Are there conditions involved in the system which necessarily impair its efficiency? Is it conducted economically, or can important financial economies be brought about, and the service thus be improved?

"Are we in this unsupervised charity work, carelessly building a vaster and vaster pauperizing institution, already in the present and especially destined in the future, to necessarily abort by its enormity and unwieldiness all efficient efforts at caring for the really deserving?

"Is the burden already placed on the medical profession, not to speak of its marked tendency to increase, too heavy for its cheerful and efficient bearing? Is the economic imposition by patients not entitled to free service causing widespread lack of confidence on the part of physicians in the system, and thereby undermining the efficiency of the service? Who should be treated free and who should not? And, in general, how can an efficient service be best conducted and conserved?

"Does it pay, from the humanitarian, scientific, or social-economic standpoint, to spend time, skill, and money on patients whose home surroundings are bound to cause or prolong the disease which we are trying in vain to eradicate by our medical charity? Can general social service methods, for example, home nursing and home helping, be employed more widely as an intrinsic feature of this great charity system, capable of modifying the hygienic and mental and moral conditions which stand between the patient and recovery?"[2]

*Remedies Suggested.*—The problem, as we see, has very many bearings: social, charitable, administrative, ethical, therapeutic, educational, economic, and financial. The field of the dispensary has to be enlarged, higher standards of medical work established, the administration made more efficient, its resources greatly amplified, the principle of restricted numbers and of district lines adopted,[3] the unworthy applicants eliminated,[4] physicians recompensed, treatment carried to the home of patients unable to come to the dispensary, a study of the home surroundings made, social guidance and instructions in hygiene given. The latter may prove to be a great help in dispensary as well as public health work. Dr. Richard C. Cabot found that 41

per cent. of the patients of the Massachusetts General Hospital Dispensary suffered from functional disorders, therefore curable if the cause could be removed. Whether digestive disturbances are due to ignorance of proper diet or cooking or neurasthenia, to overcrowding, bad industrial conditions, etc., cannot be brought to light from an examination under ordinary dispensary conditions.[5]

What can be done in this and other directions has been shown by the Massachusetts General Hospital Dispensary,[6] the Boston Dispensary,[7] and the Association of Tuberculosis Clinics of the City of New York.[8]

*Organization of the Associated Out-Patient Clinics.*—Realizing that the proper solution of the problem can only be made by those responsible for the management of the dispensaries, the Public Health, Hospital and Budget Committee of the New York Academy of Medicine suggested that an association of dispensaries be formed, which would study the elements involved and devise remedies for existing evils. At the meeting called by the Committee in February, 1912, at which twenty-six dispensaries were officially represented, a resolution was passed to appoint a temporary committee to organize the Association. Its organization took place in December of last year with a membership of thirty-two of the most important dispensaries of Manhattan, the organization being temporarily limited to that borough.

*Aims of the Association.*—The aims of the Association are fourfold: (1) The coordination of the work of existing dispensaries and out-patient clinics. (2) The elimination of unworthy applicants for treatment. (3) The promotion of proper standards of treatment. (4) The promotion of economy and efficiency in dispensary management.

As a means for the accomplishment of these ends the Association will first direct its attention to the following objects:

1. The Coordination of the Work of Existing Dispensaries and Out-Patient Clinics. (*a*) The study of the home distribution or residential sources of cases now treated in the clinics of the Association. (*b*) The formation of a plan for the district limitation of the work of those departments of general dispensaries which are organized for home treatment, district visiting, or social service. (*c*) The consideration of the status in the Association of special dispensaries, meaning thereby those dispensaries whose practice is limited to the treatment of certain classes of cases, such as orthopedic dispensaries, eye and ear dispensaries, babies' dispensaries, etc., and also the clinics which are directly affiliated with undergraduate or post-graduate medical schools.

2. The Elimination of Unworthy Applicants for Treatment. (*a*) An inquiry into the methods of investigation and elimination now or heretofore followed by members of the Association and a statement of the results of such methods. (*b*) An inquiry into the practicability of establishing a central bureau of investigation and registration, either in common with existing charitable relief societies or in cooperation with such societies. (*c*) An inquiry into the practicability of the limitation of dispensary treatment, except in emergency cases, to individuals whose circumstances have been previously investigated, and who are registered as suitable subjects for free medical relief. (*d*) An examination of the merits and defects of the existing dispensary law. (*e*) In the absence of a central bureau of investigation and registration, a study of the practicability of establishing in the clinics of the association uniform methods of inquiry into the social and financial status of patients.

3. The Promotion of Proper Standards in Treatment. (*a*) A study of the principle of the limitation of numbers in dispensary practice. (*b*) The formulation of guiding rules to be followed in the limitation of the number of patients in individual departments. (*c*) An inquiry into the need for additional therapeutic equipment. (*d*) The study of the relative need of home visiting and of social service in the different departments of a general dispensary, with a view to the encouragement of development of such work along the lines of greatest immediate need and benefit. (*e*) A study of the number of physicians required and of the hours of service demanded to conduct properly the dispensary work of the city. (*f*) Cooperation with the State Board of Charities, and with the Department of Health in the promotion of proper hygienic standards in out-patient clinics.

4. The Promotion of Economy and Efficiency in Dispensary Management. (*a*) A study of the unit of cost in dispensary treatment. (*b*) A comparison of the results of unpaid and of paid medical work in the clinics of the Association. (*c*) A study of the methods of ordering and filling prescriptions, of the relation between cost of service and dispensary payments, including a consideration of the principle of the nominal dispensary fee. (*d*) An inquiry into the need of additional departments in out-patient clinics.

*Constitution.*—The Constitution does not bind any member by rigid laws. Every dispensary of the city may become a member of the Association and be represented by a delegate. Each member pledges itself to endeavor to conform to such rules and recommendations as may be adopted by the Association. If, however, the application of any rule or recommendation shall prove impracticable in the administration of a given clinic, an explanation of the facts may be presented in writing to the Association at the first opportunity and the acceptance and filing of such explanatory statement by the Association shall be deemed to be equivalent to the granting of an exception to the rule in favor of the clinic in question.

It is expected that before long the Association will embrace all the clinics of the city and with their full cooperation it will be able to apply practically many of its ideals.

# INDICANURIA AND THE PHOSPHATES.

By JOHN C. WARBRICK, M.A., M.D., M.S.,

CHICAGO.

On account of the variation in the amount of urinary chlorides from time to time under certain conditions, and the fact that they may bear some relation to the amount of indican present in the urine, it might be supposed that the phosphates would also have some relation to the amount of indican, for in many instances they have been found to be greatly increased and sometimes reach as high as the maximum daily amount of chlorides, while again in other cases they may be entirely absent.

Since the phosphates form an integral part of the body fluids and tissues, it might be supposed they would be affected in cases in which the chlorides are altered; but this does not seem to be the case, for the chlorides being variable at all times and readily subject to change according to certain conditions, such as diet, exercise, disease, it has been found that the phosphates in the body may or may not be affected when the chlorides are being more stable and not so governable by body conditions.

During the twenty-five examinations made for the chlorides, phosphates, and sulphates, the amount of phosphates in three instances was found to range as high as 15-232.5, much beyond the normal daily maximum amount and far more than the normal daily minimum amount. This was also beyond the normal daily minimum amount of the chlorides, but a little less than the maximum amount. In one instance the amount of phosphates reached as high as the index 14-217, and in two cases they were as high as 10-155 beyond the normal daily minimum amount each time.

Again at three examinations the amount of phosphates was found to be at the index figure 8-124 beyond the normal daily minimum amount.

In nine instances in which the phosphates were not very high in amount indican was present and found to be at a rather high mark, while in five instances where the amount of phosphates was high the register of indican was not very great. Although the phosphates are increased in a number of diseases, such as cancer of the stomach, phthisis, inflammation of the brain, still they seem to have little or no influence whatever in the production of indican.

# Medicolegal Notes.

**Employment to Treat Another—Compensation.**—Action was brought against an electrical company for professional services rendered by a surgeon and owner of a hospital to a person injured by coming in contact with the company's electric wires. A leg was amputated, and other operations performed necessary to preserve the man's life. When these were nearly concluded a doctor retained by the defendant company to look after its injured employees, and authorized to make arrangements for their care in outside towns when injuries occurred, arrived upon the scene and directed the hospital authorities to give the patient every possible care. This was done at great expense and trouble. Within a day or two after the accident the assistant to the defendant company's president and general manager told the hospital authorities to take every care of the patient, and that the company would see to their compensation. It was held that the company was liable for the hospital charges, the patient having been injured through its instrumentality and its agents with ostensible authority having directed the hospital authorities to care for him. It was not, however, liable for the surgical services performed before any instructions were given by its officers, without proof that the injuries were caused by its negligence.—Rich v. Edison Electric Co. (Cal), 123 Pac. 230.

**Practicing without a License—Religious Beliefs.**—Under an information for practicing medicine for a fee without a certificate, the evidence showed that the defendant professed to treat sick and diseased people, maintained an office for that purpose, and treated patients for the cure and relief of bodily infirmities or diseases by examination of the person and rubbing the parts of the body supposed to be affected, doing this as a business for fees. It was held that he was subject to the provisions of the statute creating a board of medical registration and examination, and regulating the practice of medicine, surgery and osteopathy. The provision in the act that nothing therein referred to shall be construed as interfering with religious beliefs in the treatment of diseases did not exempt him from its operation, although he believed the words of Jesus in regard to healing can be carried out; that from Bible study and supplemental study of psychology and suggestive therapeutics he could to some extent carry out such healing practices; and that it was his duty to do so.—State v. Peters, Kansas Supreme Court, 123 Pac. 751.

**"Illness" in Insurance Application.**—An insured, in her application, stated that she had not been confined to her house by illness or consulted a physician since childhood. In an action on the policy, it appeared that about two years before the application she had been confined to the house by an acute cold, causing suppressed menstruation and a soreness and congestion of the womb, when a physician paid her one visit. It was held that this did not invalidate the policy, as a reasonable construction of the question whether she had ever consulted a physician implies that it should be interpreted as relating to a consultation as to some disease or illness with which the applicant was or had been afflicted, not to some feeling of trivial discomfort or temporary indisposition, not affecting the general health.—People v. Grand Circle (Cal.), 123 Pac. 349.

**Compensation for Professional Services—Evidence.**—A physician sued for professional services rendered by him to a deceased sister of the defendant, who, during her lifetime, was a member of the defendant's family, and also for the amount of a consultation fee paid to another physician, which claim had been assigned to the plaintiff. The case was tried before the court and jury. The issues were whether or not the defendant had promised to pay for the services of the physician, and whether or not the defendant's sister had paid the defendant in full for his services. The plaintiff testified in detail to the number of visits and to the services which he rendered. The value of the services rendered was conceded to be $55, the amount claimed. The defendant testified that he did not promise to pay for these services. His wife testified that she had seen the defendant's sister pay for the plaintiff's services upon each visit. Her testimony was weakened on cross-examination. The trial court left the issues involved to the jury as questions of fact, and instructed them to determine as to the credibility of the witnesses. The jury found a verdict for the plaintiff, which the court at once set aside as being against the weight of the evidence. An appeal was held that the trial court's action was an improper exercise of judicial discretion, the only issue being one of fact, which it was for the jury, not the court, to decide. Levene v. Denker, 135 N. Y. Supp. 592.

New York February 15, 1913.

## EPIDEMIC CATARRHAL JAUNDICE.

DURING the past few months a large number of cases of this condition have been observed among children in New York City, and probably in other localities. The experience of the present and of previous winters indicates a marked seasonal incidence of this disease, which, being frequently associated with common colds and symptoms of influenza, has been regarded as a catarrhal manifestation. The simultaneous occurrence of gastro-intestinal symptoms, such as vomiting, diarrhea, anorexia, and abdominal pain, and of a more or less intense jaundice, has suggested that in these cases the underlying pathological condition is a gastroduodenitis, with a resulting occlusion of the common bile duct at its terminus in the papilla of Vater. The occurrence of jaundice in many infectious diseases, notably in pneumonia, strongly suggests a bacterial infection of the biliary passages and of the liver, particularly in cases in which this organ undergoes an acute enlargement. The predilection of the typhoid bacillus for the gall bladder is not an isolated instance of the invasion of this viscus and of its anatomically related parts by pathogenic bacteria.

It is pointed out in an interesting paper on epidemic catarrhal jaundice by Leonard Guthrie (*British Journal of Children's Diseases*, January, 1913) that although sporadic cases of catarrhal jaundice are not uncommon in children, and that although a large number of these sporadic cases occurring at the same time in a given community may convey a false impression of the epidemicity of this disease, nevertheless it must be recognized that actual epidemics of catarrhal jaundice may occur. The epidemic character is determined by the simultaneous outbreak of jaundice among a large number of children in a restricted territory, and often among several children in the same family. A distinction must be made between this disease and epidemic infectious jaundice, described by Weil in 1886. The latter condition differs from the former mainly in the greater degree of severity. Besides, in Weil's disease there are associated with the icterus urticaria, petechiæ, hemorrhages from the nose, stomach, and other organs, fever, enlargement of the spleen, nausea, vomiting, diarrhea, and albuminuria. There is a fatal outcome in from 10 to 60 per cent. of the cases, in which the clinical picture and pathological changes are identical with those of acute yellow atrophy of the liver. Epidemics of catarrhal jaundice in England have always been of mild character, with no fatalities, but in other countries these have been reported. In a Moscow epidemic of ninety-six cases in children between two and four years of age, there were six fatal cases.

There can be no doubt that epidemic catarrhal jaundice is of microbic origin. The conception that this condition is the result of a mechanical obstruction of the bile duct associated with gastroduodenal catarrh is regarded as incorrect, for this obstruction cannot account for the great enlargement of the liver that is present in so many cases. It is suggested that epidemic jaundice, whether of the mild or severe type, is the result of an acute general hepatitis produced by microorganisms or toxins. Various bacteria have been suspected, such as the pneumococcus, the influenza bacillus, and the *Bacillus coli*, the last two of which have been isolated from the liver in two cases in children in which acute yellow atrophy of this organ was present. The analogy between the pancreas and the parotid glands, and the occasional coincidence of cases of mumps and jaundice in the same community, have suggested that mumps, acute pancreatitis, and acute hepatitis may sometimes be "allotropic" forms of one and the same disorder.

It is probable that future investigations of this subject will throw considerable light upon the actual bacterial or other cause of this interesting condition. Present knowledge tends to minimize the importance of the possible mechanical factor in the etiology of epidemic jaundice, and seems to indicate a widespread infection, usually of a mild grade, that exerts its greatest influence upon the liver.

## THE AGGLUTINATION IN SYPHILIS.

AMONG the antibodies developed by an animal in response to an infection the agglutinins have been largely used as important aids to diagnosis. In syphilis an agglutination has been described by several authors but until recently there has apparently been no well-directed effort to ascertain what diagnostic value such a reaction might have in this disease. Albert Touraine* has instituted a searching investigation of the subject and has published some very interesting results of his work. To overcome the difficulty of obtaining pure cultures of the causative organism he has used a fragment of tissue from a condyloma on the genitals of a woman in the active stage of the disease. When such a piece of tissue is removed with the minimum amount of blood or serum, placed in physiological salt solution and examined, the field of the microscope is soon seen to be swarming with spirochetes. On the addition of serum from a syphilitic patient a characteristic agglutination takes place. At first two organisms join end to end, and gradually others add themselves, forming a stellate figure of from six to twenty members. The new organisms approach the group in a hesitating manner but when

*Les anticorps syphilitiques, essais de séro-agglutination de la syphilis. Paris: G. Steinheil, 1912.

within a certain distance the junction occurs with marked suddenness. This characteristic agglutination is distinctly a reaction of living organisms and is entirely different from the confused agglomeration which takes place in a preparation containing only dead spirochetes. The most frequent source of error and the most difficult to avoid was the autoagglutination which took place at times due to the admixture with the tissue of more or less serum from the donor. The author avoided this complication by discarding all those preparations which showed blood platelets, considering these as evidence of the presence of serum or blood.

Touraine tried this reaction on 137 patients and found that it became positive in about ten days after the appearance of the chancre. His percentage of positive results is as follows: Primary syphilis, 83.0; secondary syphilis, 95.1; tertiary syphilis, 90.9; parasyphilis, 75.0; hereditary syphilis, 100.0. Treatment caused the disappearance of the reaction only when prosecuted vigorously.

In spite of the great scientific interest which naturally attaches itself to such a work the test will probably not reach any great degree of clinical usefulness. In the present days of the popularity of salvarsan one would but rarely find a suitable donor, at least as described by this author, and the Wassermann reaction and the luetin test are much simpler in their clinical application. Of course if a satisfactory supply of the organisms could be obtained its use would be attended with less difficulty than would be the case at the present time.

## CANE VERSUS BEET SUGAR.

The fact is more or less generally admitted that the teeth of the present generation are not so good as those of the past. This is palpably obvious in Europe where army statistics show that the teeth of those joining the colors now are decidedly more carious than were those of recruits twenty years ago. Of course, decay of the teeth is no new occurrence but it is suggestive to note that there has been a marked increase in its incidence.

Dr. A. Stayt Dalton, in an article in the *Medical Press and Circular,* Dec. 11, 1912, points out that dental caries appears to have increased *pari passu* with the increase of consumption of beet root sugar. For example, statistics show plainly that since the year 1840, a marked alteration has taken place in the world's sugar trade, and in the habits of people in regard to the use of it. It is noteworthy, too, that the augmented importation and consumption of beet sugar in Great Britain, and in consequence the decrease, particularly, since 1870, in that of cane sugar, has been contemporaneous with a decided increase in the occurrence of dental decay. A good deal of the increase of dental caries may be attributed to the larger consumption of sugar in various forms which has taken place since the introduction of a cheaper sugar. It is questionable, however, whether to this cause alone can be ascribed the really remarkable increase of dental decay which has signalized the predominance of beet sugar. True it is, that the chemical composition of cane and beet sugar is said to be identical; yet there may be differences. Dr. Goulston stated in a paper read before the British Medical Association in Liverpool last July that three leaders in the chemical and physiological world have admitted that it is not inherently impossible for beet sugar to contain a factor which is not present in cane sugar. Although the suggestion of Dalton seems in the highest degree fanciful, it is nevertheless a question not unworthy of serious consideration to ascertain whether beet root sugar has a more deleterious effect on the teeth than cane sugar. It concerns Great Britain more intimately, perhaps, than this country, that is from the economic point of view, but on the other hand, more sugar is consumed in America and even from the purely scientific standpoint it might be as well to try to elucidate the point.

## The Inclusion Bodies in Scarlet Fever.

The recent announcement by the Health Department of Boston that it is prepared to examine blood-films from suspected cases of scarlet fever, with the view of aiding in the diagnosis of this disease, suggests that considerable importance is attached to the so-called Döhle leucocyte inclusions which are almost invariably present in the early days of scarlatinal infection. But these bodies have also been found in many other infectious diseases. A number of observers have reported contradictory results with reference to the incidence of the inclusion bodies and to their diagnostic significance. A careful investigation of this subject has been made by J. Granger and C. Kingsley Pole (*British Journal of Children's Diseases, January,* 1913), with the view of determining the following facts: (1) if the inclusion bodies are present in all cases of scarlet fever; (2) the date of their disappearance; (3) if they are present in diseases which might be mistaken for scarlet fever, *e.g.* diphtheria, measles, tonsillitis, and rashes due to sepsis, enemata, drugs, and intestinal intoxications; and (4) the diagnostic value of these bodies. As the result of the study of a large number of cases, the authors conclude that except in the extremely fatal toxic type of scarlet fever, Döhle's inclusion bodies are found in every true case of scarlet fever during the first four days of illness. The absence of the bodies practically excludes scarlet fever. After the fourth day the bodies appear with lessening frequency, and are absent in most cases after the eighth day. The presence of these bodies in a large proportion of cases of measles, diphtheria, and tonsillitis, makes the inclusion bodies of no value in a differential diagnosis between the above diseases and scarlet fever. In fact, the bodies are found in most diseases caused by ordinary pyogenic organisms. The absence of the Döhle bodies in the case of toxic rashes may aid one in the diagnosis of these conditions. On the basis of their important findings the authors are justified in drawing the conclusion that it is impossible to diagnose scarlet fever from film examinations alone.

## Osteomalacia and the Internal Secretions.

Osteomalacia was one of the first diseases to be brought in causal relationship with anomalies of the internal secretions, but on account of the interlocking character of the latter in the production of pathological syndromes much still remains to be

learned concerning this malady. In a recent number of the *Berliner klinische Wochenschrift* (December 9) Zuntz sums up the recent advances in this province of research. The ovary appears to be able to inhibit the retention of calcium, while so far as known all the other glands of internal secretion have the opposite action. Castration has long been a tried remedy for osteomalacia, but the same end may be attained without mutilating the women if polyglandular preparations are given inwardly. The action of the hormones when given singly, while occasionally brilliant, may be absent entirely. Striking cures, Zuntz says, have recently been obtained with pituitrin, and adrenalin has been tested in forty-six cases with five cures. The administration of ovarian extract appears to antagonize the effects of these hormones under certain conditions. At present the three glands which have some recognized therapeutic power over osteomalacia are the thyroid, the adrenals, and the hypophysis. As the normal or even pathological activity of the ovary is not the efficient cause of the disease, it is evident that some defect in the other structures must be primarily concerned; so that only the uncorrected action of the ovary is manifest. As the disease does not result outright from removal of any one structure it is probable that several are simultaneously involved, and whenever this is the case we have to suspect some deep-seated insufficiency of development.

## News of the Week.

**Hospitals for Indians.**—The Committee on Indian Affairs of the United States Senate has approved an Indian Appropriation bill providing for hospitals and other means for treating tuberculosis among the Indians. The appropriations amount to $307,000.

**Mount Sinai Laboratory.**—It has been decided that the new pathological building for the Mount Sinai Hospital, New York, on which work will be begun about July 1, shall be called the Mount Sinai Hospital Pathological Building and Laboratory, Adolph Lewisohn Foundation, in honor of the donor.

**Decrease in Death Rate.**—For the week ending February 1, the death rate in New York City was 13.98 per thousand, the total deaths being 1,440, as compared with the same period of 1912, when the rate was 16.06, and the total number of deaths 1,593. The number of deaths reported as due to organic heart diseases decreased 69, and to pneumonia, 65. There was a slight increase in the number of deaths dut to diphtheria and influenza.

**State Hospital Commission.**—Gov. Sulzer has appointed Mr. Milton B. Gibbs of Rochester as the legal member of the New York State Hospital Commission, to succeed Col. William C. Sanger, serving until December 31, 1914, at a salary of $5,000 and an additional $1,200 annually for expenses.

**Harvey Society.**—Prof. Theodore C. Janeway of the College of Physicians and Surgeons, New York, will deliver the seventh lecture of the Harvey Society at the New York Academy of Medicine on Saturday evening, February 15, at eight-thirty. The subject of the lecture will be: "Nephritic Hypertension: Clinical, and Experimental Studies."

**Philippine Service.**—The United States Civil Service Commission announces an open competitive examination for men only, for the purpose of filling a vacancy in the Bureau of Science, Manila, P. I., at a salary of two thousand dollars a year. Persons desiring the examination should apply at once for Form B. I. A. 2 to the United States Civil Service Commission, Washington, D. C. Applicants must be between eighteen and forty years of age, and graduates in medicine with in addition at least one year's post-graduate experience in conducting laboratory research work in experimental therapeutics.

**Tuberculosis in Alaska.**—Dr. Emil Krulish of the U. S. Public Health Service, in a report to the U. S. Commissioner of Education, states that at least 15 per cent. of the entire population of Alaska is infected with tuberculosis and that this disease will exterminate the native population in the course of two generations, unless promptly checked.

**University of Georgia.**—The new buildings of the Medical Department of the University of Georgia at Augusta were formally opened by Gov. Brown on January 29. At the exercises, which were attended by a large number of prominent persons, honorary degrees were conferred upon Dr. William M. Polk, Dean of the Cornell University Medical College, New York, and Dr. John A. Witherspoon of Nashville, Tenn., president of the American Medical Association.

**Inter-State Milk Conference.**—Ten States in addition to the Federal Government were represented at a conference held recently at the New York Academy of Medicine under the auspices of the New York Milk Committee. Legislative bills will be drafted in the various states incorporating the recommendations made by the conference, of which the most important are that every dairy cow in the State shall be tested for tuberculosis, and that records of these tests shall be kept; that all tuberculous cows shall be killed, the State to compensate the owner; and that there shall be strict State quarantine to prevent the sale or transportation of any cow known to be diseased.

**Gifts to Charities.**—By the will of the late Dr. Orville Horwitz of Philadelphia, the sum of $15,000 is bequeathed to the Jefferson Hospital of that city, for the endowment of three free beds, one in the genitourinary ward, to be inscribed, "In Memory of Orville Horwitz"; one in the surgical ward, to be inscribed, "In Memory of Phineas Horwitz, late Medical Director and Surgeon General, United States Navy"; and one in the gynecological ward, to be inscribed, "In Memory of Caroline Norris Horwitz."

The National Jewish Hospital for Consumptives at Denver, Col., has received a gift from Mrs. Jacob Greenhut of New York, for the purpose of erecting an addition to the hospital and equipping it with special rooms and apparatus for the treatment of tuberculosis by inhalation of gases.

**Dr. M. Allen Starr** of this city will sail for Egypt on February 18, to be absent until September 1.

**A Study of Diabetes.**—Dr. W. E. Fitch of 355 W. 145th St., New York, writes that he is undertaking a research into the pathology, etiology, and dietotherapy of diabetes mellitus. Von Noorden says "the best treatment for the diabetic is the food containing the greatest amount of starch which the patient can bear without harm," and Dr. Fitch would be glad to hear from any physician who has had a similar or contrary experience.

**Suggested Consolidation of Medical Economic Societies.**—At a meeting of delegates from the various medical economic societies of Greater New York held in the Borough of Manhattan, February

7, 1913, it was decided to present to the following societies a plan of consolidation: Physicians' Protective League of Downtown New York, Medical Alliance of New York, Physicians' Protective League of New York, Yorkville Economic League of New York, Physicians' League of the Bronx, and Physicians' Economic League of Brooklyn, N. Y. These societies now have a combined membership of two thousand physicians.

**Fourth International Congress on School Hygiene.**—The meetings of this congress will be held in Buffalo, N. Y., on August 25 to 30, 1913, under the presidency of President Charles Eliot of Harvard University, and it is expected that delegates from at least twenty-five nations will be in attendance.

**Medical Society Elections.**—Audubon Medical Society.—At the annual meeting of the society, held recently in New York, the following officers were elected: *President,* Dr. Theodore K. Tuthill; *1st Vice-President,* Dr. Robert Emmett Walsh; *2d Vice-President,* Dr. Goodrich T. Smith; *Treasurer,* Dr. W. Ten-Eyck Elmendorf; *Secretary,* Dr. Sidney Furst.

Clarendon County (S. C.) Medical Society.—The following officers were elected at the annual meeting held at Manning on January 29; *President,* Dr. George L. Dickson, Manning; *Vice-President,* Dr. Thomas J. Davis, Summerton; *Secretary-Treasurer,* Dr. Henry L. Wilson, Jordan.

Upper Mississippi Valley Medical Society.—At the meeting held at Wadena, Minn., on January 27, the following officers were elected for the ensuing year: *President,* Dr. William Reed, Deerwood; *Vice-president,* Dr. Michael A. Desmond, Akeley; *Secretary,* Dr. Arthur W. Ide, Brainerd; *Treasurer,* Dr. Paul E. Kenyon, Wadena.

Ramsey County (Minn.) Medical Society.—At the annual meeting held at St. Paul on January 27, the following officers were elected: *President,* Dr. Charles J. Meade, St. Paul; *Vice-president,* Dr. J. M. Armstrong, St. Paul; *Secretary,* Dr. Charles E. Smith, Jr., St. Paul.

**The Late Dr. Tuttle.**—At a special meeting of the board of trustees of the New York Polyclinic Medical School and Hospital, held February 9, 1913, the following resolution was unanimously adopted, and the secretary was directed to request the Medical Record to publish the same:

*Resolved*, That in the death of Professor James P. Tuttle, the board of trustees of the New York Polyclinic Medical School and Hospital has lost one of its most worthy members, and the medical faculty of this institution one of its most successful teachers, who for a quarter of a century has been associated with its medical staff.

Dr. John A. Wyeth writes: "I ask the privilege of paying this slight tribute to the memory of my friend and associate, the late Dr. James P. Tuttle. His career may well serve as an example and an inspiration to all and especially to the younger men, who are standing near the threshold of the life of a practitioner of medicine. Born and reared in a country town in Missouri, having no backing except his faith in himself, he came to this city immediately after finishing an internship in one of the large hospitals of Philadelphia. He paid me the compliment of asking to work upon my staff, and he and I were thus intimately associated for 15 years, until he grew into the leadership in his own selected department of surgery. Of his fame as a specialist I need not speak. His text-book and the technique of many of the most formidable procedures which he developed speak for themselves as to his originality and his great ability. Though never any too strong of body, his indomitable energy enabled him to accomplish much more than many physically more able to achieve. His moral strength and his devotion to duty were his most valuable assets, earning for him the confidence of his friends and the respect of all. His illness, so patiently and so bravely borne, was for the last few years a great loss to the Polyclinic, which his genuis helped to build. His death is a grief to all of us, and to me, acutely personal. Our long association only served to bind us more closely together, and the grave but accentuates an affectionate friendship which began years ago when he was my pupil and assistant."

**Obituary Notes.**—Dr. Albert Clinton Aldrich of Somerville, Mass., a graduate of the Harvard Medical School, Boston, in 1883, a member of the American Medical Association and the Massachusetts State and Middlesex County Medical Societies, and assistant physician at the Charlestown State Prison, died suddenly on January 29, aged 56 years.

Dr. W. W. P. McMillen of Decatur, Ind., a graduate of the Medical College of Fort Wayne, Ind., in 1878, and a member of the Indiana State and Adams County Medical Societies, died at his home on January 15, aged 66 years.

Dr. George Edmund Reynolds of Hayward, Cal., a graduate of the University of California, Medical Department, San Francisco, in 1877, and a member of the American Medical Association and the California State and Alameda County Medical Societies, died at his home after a short illness on January 11, aged 56 years.

Dr. Daniel William Hayes of Brownville Junction, Me., a graduate of the Medical School of Maine, Portland, in 1897, and a member of the Maine State and Piscataquis Medical Societies, was instantly killed in a rear-end collision between trains on the Canadian Pacific Railroad at Onawa on January 21, aged 42 years.

Dr. Newton P. Hunter of North Lewisburg, Ohio, a graduate of the Eclectic Medical College, Cincinnati, in 1883, died suddenly at his home on January 20, aged 66 years.

Dr. J. E. Massey, Sr., of Rock Hill, S. C., a graduate of the University of Maryland, School of Medicine, in 1871, died at his home after a long illness on January 20, aged 64 years.

Dr. William Jacob Wagner of Toronto, Canada, a graduate of the Toronto School of Medicine, in 1870, died at his home after a long illness on January 10, aged 63 years.

Dr. Louis B. Balliet of Allentown, Penn., a graduate of the Department of Medicine, University of Pennsylvania, in 1854, and the oldest active physician in his section of the State, having practiced continuously for fifty-five years, died at his home on January 28, aged 81 years.

Dr. Alfred Irving Morse of Boston, Mass., a graduate of Tufts College Medical School, Boston, in 1910, formerly an interne at St. Mary's Infant Asylum and Lying-In Hospital, and more recently connected with the United States Marine Hospital, Chelsea, died at the hospital from septic poisoning contracted in the course of duty, aged 27 years.

Dr. Helen A. Goodspeed of Worcester, Mass., a graduate of the Eclectic Medical College of the City of New York in 1870, died at her home recently from diabetes, aged 69 years.

Dr. Daniel B. Cliffe, retired, of Franklin, Tenn., a graduate of the University of Louisville, Medical Department, in 1842, died at his home from pneumonia on January 22, aged 90 years.

Dr. Robert D. E. Follweiler of Allentown, Penn., a graduate of the Baltimore University School of Medicine, Maryland, in 1898, died at his home on January 27, aged 39 years.

Dr. William F. Decker of Philadelphia and Newfoundland, Penn., a graduate of the Jefferson Medical College, Philadelphia, in 1878, died at his home in Newfoundland of penumonia on January 26, aged 57 years.

## Correspondence.

### TUNING-FORK TESTS.

To the Editor of the Medical Record:

Sir:—A recent article in the Medical Record by A. B. Bennett, Jr., M.D., contains certain inaccuracies which it seems to me should be corrected.

1. The upper limit which Dr. Bennett gives as 48,000 d.v. is conceded by modern investigators to be too high. The upper limit of hearing is certainly not above 25,000 d.v. and recent investigations by means of the monochord, which is apparently a more accurate instrument than the Edelmann whistle, would place the upper limit at not to exceed 20,000 d.v.

2. His third proposition that "interference with the perception apparatus causes loss of the high tones" while generally true, particularly so of slow degenerations of the auditory nerve, has many exceptions; *e.g.* the nerve deafness resulting from cerebrospinal meningitis not infrequently leaves a large island of hearing near the middle of the range of hearing, while the low tones are destroyed.

3. "Normal ears hear twice as long by air conduction as by bone conduction." This proposition may be true for certain forks and at certain ages, but as a general proposition it is not exact. With advancing age bone conduction is shortened; the author takes no account of this factor.

4. His sixth proposition is: "When the perception apparatus is diseased bone conduction is diminished and the relative time for air conduction is lengthened." The first part of this proposition is true, the second part should rather read that the time for air conduction and bone conduction are both shortened.

If the author will consult the "Bericht der Kommission zur Ausarbeitung einer einheitlichen akumetrischen Formel," by Jörgan Möller, in the transactions of the Sixteenth International Congress of Medicine, Budapest, September, 1909, page 285, he will find a much better formula for recording the results of his tuning-fork test than the one given in his article. To sum up the whole matter, tuning-fork tests are of very little use in prognosis; they are of a great deal of use in diagnosis. But when the diagnosis of the condition is made, then the prognosis is easier, for we know that most cases of the middle ear type of deafness not due to otosclerosis, may be improved to some extent by treatment, and that deafness due to disease of the auditory nerve is but rarely improved by treatment. As a rule, the cases of nerve deafness that appear to be improved as a result of treatment, upon careful examination will be found to be complicated by a certain amount of middle-ear deafness and it is the middle-ear deafness that improves on treatment.

In this connection I may be permitted to observe that it seems to be the opinion of otologists working in our large eastern clinics, that tuning-fork tests are of little or no use. Thus I found in one of the largest ear clinics of Philadelphia but three or four tuning forks and an old fashioned Galton whistle. With this outfit it is absolutely impossible to determine either the upper or the lower limits of hearing. Small wonder then that in this clinic no case of otosclerosis had been diagnosed for seven years. In another large clinic in the same city, the physician stated that the tuning-fork tests were made by the admitting clerk. After considerable effort, one tuning fork was found in this clinic. After this demonstration I was not surprised that the attendant did not know what I meant by otosclerosis. In one of the largest clinics of New York City the physician informed me that tuning-fork tests were valueless. His chief, overhearing the conversation, told me that they had a set of Edelmann forks but did not know how to use them. It is to such ignorance of tuning-fork tests that we owe the lamentable spectacle of patients with otosclerosis going to otologists for weeks and months of treatment until their money is all gone in a useless effort to improve an incurable condition. If this letter is the means of directing more accurate study to tuning-fork tests, it will have accomplished its purpose.

G. W. Boot, M.D.

122 S. Michigan Ave., Chicago.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

Insurance pledge rescinded—campaign continued by B. M. A.—other committees opposing—compromise dangerous—first victim of panel scheme—obituary.

London, January 24, 1913.

The representatives of the British Medical Association were unable to conclude their discussion on the 17th, and adjourned until the next day, on which, therefore, the vote was taken for releasing from the pledge those who had signed it. In accord with the general anticipation the release was carried by 115 to 35. This seems to have been the best course under the circumstances. The members had been landed in an impossible position by their incompetent leaders, and another compromise threatened to wreck the Association. The meeting saw this, and the necessity of adopting some constructive policy. Accordingly it passed a further resolution instructing the council to take all necessary steps to watch and protect the interests of the profession by getting, where possible, representatives on the advisory and insurance committees, and statutory recognition of local medical committees; also by taking every opportunity of pointing out defects in the act and in the regulations, and endeavoring to secure their removal. The next resolution—adopted without discussion—was that acceptance of service outside the practitioner's own district, involving change of residence for the purpose, would be regarded as detrimental to the honor and interests of the profession. Then, with one dissentient, an emphatic protest was entered against the discreditable methods of the government in compelling unwilling service on terms against the public interest. Finally the meeting declared the act to be unsatisfactory, and where men still hold out the council should give them every assistance in its power. This was unanimously carried amid loud applause.

The result of this decision has been a daily addition of names to the panels, and yesterday it was officially announced that the number of those who have signed on to the panel for London is 998.

Immediately after the representative meeting the London committee met to consider its position, and decided to continue the campaign in the capital. The same evening it therefore issued a letter asking practitioners whether they intended acting on the panel, either willingly or unwillingly. They have received sufficiently encouraging replies and are supported in a policy of resistance by public meetings in different districts to determine them so far to maintain their hostile attitude and carry on the campaign in London, Middlesex, and perhaps other of the Home counties, but in these they will probably find they must seek support from those on the panels, and it is thought this will not be denied.

But it must not be supposed that this committee represents fully the profession, or even the British Medical Association. It will doubtless have considerable influence in agitating for amendments to the act and inducing those on the panel to seriously consider whether they will continue after the expiration of their three months trial, on April 14. There are men optimistic enough to think that a general resignation at that date would still defeat the government. How can such unanimous action be hoped for in face of the failure of the 27,000 to hold together? Different groups or, as their opponents prefer to call them, factions, are already forming committees to promote their various wishes. Some of them frankly oppose the British Medical Association. Others favor some special proceeding. One proposes to form a medical union on the lines of trade unions to defend the rights and privileges of the profession both in town and country. Considering how strongly the methods of trade unionists have been repudiated whenever they have been alluded to, it seems unlikely that this group will make much progress, although it has B. M. A. members among its promoters.

Another organization, mentioned in former letters, is called the National Insurance Practitioners Association and has this week issued a long statement emphasizing the necessity of its existence and stating that its arrangements are frankly experimental and provisional. It offers assistance to panel practitioners, acting individually or collectively, in efforts to secure such privileges as the insurance committees can want. They will work in cooperation and not in opposition to other bodies. They are considering suggestions for simplifying the records required by the commissioners and will convene a conference to collect and focus opinions and decide on a line of policy. Questions are mentioned respecting existing medical institutes and social income limits as deserving of early attention.

Other groups or factions are meeting to talk and some may be heard of further, but they are too numerous at present to do anything, unless combine.

Considering that up to date the wily chancellor has won all around many are disposed to accept defeat and make the most of the reorganization of the profession which is involved. The leaders of the B. M. A. threw away their only chance when they consented to a conference with a view to compromise. They held the pledges of 27,000 practitioners—the whole profession if you allow for those who had no direct interest in the dispute and a few hundreds who were unable or unwilling to return the voting papers. They had stated their terms, they believed them to be reasonable and right. Yet with practical unanimity on their side they consented to confer and talk. Compromise is always wrong when the question is one of right. They should have refused to deviate a hair's breadth from the terms and replied to every proposal—we have our mandate—and no power to alter it. The Chancellor would have been helpless. He wanted 10,000 practitioners and could not have found 1,000.

The Socialist papers denounced what they pretended to be a strike. It was no such thing. The public could have gone on just as before with their advisers—who would only have declined Mr. George's terms. It seems a pity that politics played so great a part in the contest. But the Socialists have always held that a State medical service would be the easiest step towards their ideal. Now they have done so much they might stay their abuse. There seems no reason why their organs should still indulge what looks like mere spite.

The "first victim" to the Act has been the subject of many paragraphs; an inquest was held on a man who died from strangulated hernia and who had applied to a panel doctor two days previously. He was supplied with medicine but no examination was made, the doctor being overwhelmed with work filling up the schedules required by the commissioners. This clerical work is said to have been imposed at the instigation of statisticians, some of them medical officers of health, who seem to think the treatment of the patients as less important than the collection of their statistics for them. The coroner hoped he might not have another case so sad and the jury condemned the government for imposing such clerical work on the doctors. Counsel in the case said it appeared to him that Mr. Lloyd George meant to run the Act on the doctors' money, collecting it as decided, weekly, and making up the accounts quarterly, paying it no one knew how long afterwards.

Dr. Howship Dickinson, who died on the 9th inst., exercised for a long period a remarkable influence on the profession. He was a Cambridge graduate and held all the offices at St. George's Hospital, retiring as consulting physician as well to the Children's Hospital. At the Royal College of Physicians he held all posts except the presidency. He had been president of the Royal Medical and Chirurgical and of the Pathological Societies. He was an all-round physician, able and learned in all branches, a constant clinical worker at his hospital and a very able teacher. He began his career with pathological work, and side by side with his clinical instruction insisted on such knowledge in every case. To profound acquaintance with medical theory and practice he added an abundant flow of wit and humor, making him an ideal consultant in difficult cases. But his great influence was further due to his straightforwardness and love of simple truth. His book on "Renal Diseases" is no doubt well known to you, for he was made a Fellow of your Academy of Medicine, but he made many contributions to societies and journals and his literary style made it a pleasure to read them.

Dr. George Alexander Gibson, Senior Physician to the Edinburgh Royal Infirmary, died on the 18th inst., after a long illness, at the age of 59. He was M.D. and D.Sc. Edinburgh and became an honorary graduate of St. Andrews, Dublin, Harvard, and McGill. For about ten years he edited the *Edinburgh Medical Journal*. He was also editor of "A System

of Medicine," 1901, and in 1905 he published "Nervous Affections of the Heart," being his Morison lectures on that subject, but he had published a work on cardiac diseases in 1898. He was F.R.C.P. Edinburgh, and it is said the presidency would certainly have been offered him but for his illness. He had a large consulting practice, his opinion being greatly valued. He had been an examiner at several universities and here we knew him as Inspector of Examinations for the General Medical Council.

Dr. G. G. Bantock died on January 15 at the age of 76. He had retired for several years after a successful career as a gynecologist, having been president of the society of his specialty and consultant to the Samaritan Hospital as well as other institutions. He wrote on "Ruptured Perineum," on the "Use and Abuse of Pessaries," and contributed to the societies and journals on similar subjects.

Dr. Charles Carter, who went out to the Balkans as a member of the British Red Cross Mission, died on January 18 of typhoid at Uskub, where he was working among the soldiers suffering from the outbreak. He was buried with military honors, the director of the Servian Army Medical Department attending the funeral with the prefect, the whole of the Consular body, the Red Cross members, and numerous officers, soldiers, and others.

Another Red Cross victim of the war is Miss Barnes, who has died also from typhoid at Salonika, where she had been working with characteristic devotion.

## OUR PARIS LETTER.

(From Our Regular Correspondent.)

CONGRESS OF SURGERY—CICATRICIAL STENOSIS OF THE ESOPHAGUS—RADIOLOGY OF THE GASTROINTESTINAL CANAL—COXA VARA—TRANSFUSION OF BLOOD—ANTITYPHOID VACCINATION.

PARIS, December 1, 1912.

THE twenty-fifth Congress of Surgery was held in Paris from the 7th to the 12th of October in the large amphitheatre of the Medical School, under the presidency of Delorme, Medical Inspector of the Army. The first subject that came up for discussion was "The Diagnosis and Treatment of Cicatricial Stenosis of the Esophagus." Moure of Bordeaux and Girisez of Paris read the opening papers. The diagnosis of cicatricial stenosis of the esophagus is based upon the previous history, auscultation, the use of the sound, esophagoscopy, and radioscopic and radiographic examinations. The most important symptom is a progressive dysphagia. Among the secondary symptoms the most striking are vomiting, regurgitation, salivation, emaciation, and cachexia. In the treatment there are two indications: (1) the dilatation of the stricture, and (2) the removal of the fibrous cicatricial tissue. If the stricture is permeable but not dilatable, circular electrolysis may be employed. If the stricture is impermeable through the natural channel, even with the aid of endoscopy, it is necessary to resort to retrograde catheterism following gastrostomy. If the stricture is completely impermeable the only resource is a simple gastrostomy. Injections of fibrolysin or of thiosinamine have not as yet demonstrated their value in these cases.

The second subject that came up for discussion was "Radiological Exploration in Surgical Diseases of the Stomach and Intestine." The papers were read by Béclère of Paris and Mériel of Toulouse. The *x*-ray examination of the digestive tract is rendered possible by the administration to the patient of salts of bismuth, and particularly of carbonate of bismuth. The other salts, chiefly the subnitrate, may produce toxic effects. Radiographic study may enlighten one concerning the topography, morphology, and motor functions of each of the segments of the digestive tract. The *x*-ray examination of the stomach shows that the situation and the form of the stomach do not correspond to the anatomical descriptions. Important facts may be revealed regarding the presence of ulcer or cancer of the stomach. In the case of the duodenum it is possible to be informed regarding displacements, ptoses, and ulcerations of this organ. Duodenal stenosis is characterized by three signs: the abnormal and persistent filling of the duodenum, and the presence of peristalsis and antiperistalsis in this organ during the process of filling. Errros of interpretation are difficult to avoid. For this reason it is necessary to vary the tests, to carry them out in different positions, and always to supplement them by clinical signs.

"Coxa Vara" was the next subject that came up for discussion. Papers on this topic were read by Kirmisson and Froelich. Coxa vara is an affection of the hip characterized by a lesion of the epiphyseal cartilage during the period of growth, causing a downward displacement of the head of the femur. The pathology has been the subject of considerable discussion. The condition may be the result of an excessive strain during adolescence upon an incompletely developed cartilage. The treatment should be in the first place preventive. The displacement should be reduced as completely as possible, in such manner that the tendency of the femoral head to move backward should be counteracted. Reduction should be effected under chloroform, and the limb should be encased in plaster of Paris in such manner as to be held in a position of abduction and outward rotation. If the displacement is not very marked it may suffice to maintain extension combined with a medium degree of abduction, which position may be attained with the use of Hennequin's apparatus. Frequently curative treatment requires an open operation such as an oblique subtrochanteric osteotomy, which is superior to an osteotomy of the neck. Resection of the head and pinning the femur are exceptional procedures.

The "Transfusion of Blood" was one of the most interesting subjects that came up for discussion. A paper on this topic was read by Guillot and Dehelly of Havre. By means of a special canula they are able to transfuse blood directly from the radial artery into the internal saphenous vein. Martel of Paris presented a paper on the "Surgery of the Skull and Spinal Column." The "Transplantation of Ovarian Grafts" was discussed by Voronof of Nice, who awakened considerable interest. Martigny of Montreal and Jayle of Paris also spoke on this subject.

The next Surgical Congress will be held in Paris in October, 1913, under the presidency of Professor Kirmisson. The following subjects will come up for discussion: The open method in the treatment of ankyloses; the surgery of the pelvic colon, and the treatment of cranial wounds caused by minor projectiles.

The "Results of Antityphoid Vaccination" was the subject of the paper read before the Academy of Medicine by Professor Vincent, who referred to the remarkable results obtained with the use of this method in a recent epidemic of typhoid fever in

the city of Avignon during the months of June, July, and August, 1912. This epidemic was particularly severe. The first cases began to appear in June, and the epidemic reached its height in July and August. The disease spread throughout the city. Out of a population of 49,000 there were nearly 1,500 cases, with 64 deaths. The epidemic spread to the military garrison of 2,000 men. Following a number of conferences that were held as to the advisability of practising antityphoid inoculation, a total of 1,386 vaccinations were effected, that is, among two-thirds of the garrison. These escaped being infected with typhoid fever, which, however, spread among the members of two regiments of infantry and engineers who had not been vaccinated. Both vaccinated and unvaccinated individuals had lived together under the same conditions, had eaten at the same mess, and had drunk the same water. All of the cases of typhoid fever were observed in individuals who had not been vaccinated. The mortality was particularly severe. The history of this epidemic furnished a remarkable demonstration of the efficacy of antityphoid inoculation. This procedure should be resorted to in the protection of members of families and schools and the inhabitants of cities, whenever the menace of typhoid fever arises. Children, soldiers, and nurses should be inoculated. By this means it will be possible to rescue from typhoid fever a large number of individuals.

1. **The Open Treatment of Fractures.**—W. Bartlett reviews the results obtained in the treatment of seventy-six cases of fracture in which Lane bone plates were used. He states that the indications for open treatment are the following: (1) When a leg case must be gotten out of bed early. (2) Old cases of non-union or *extreme* malunion. (3) This treatment is desirable in all fresh widely open fractures if shock be past. (4) Chronically infected cases in which the bones lie bare. All compound wounds, whether suppurating or not, are to be packed and allowed to granulate. Generally speaking, the patient must always be a good surgical risk.

2. **Unilateral Hematuria in Chronic Nephritis.**—P. E. Truesdale reports a case of this condition occurring in a woman seventy years of age. He notes that Fowler, of Washington, made interesting and valuable comments on the literature up to 1905, reporting a case under his own observation, from the results of which he summarized as follows: (1) The onset of the hematuria was spontaneous and without apparent cause. It was not associated with any other urinary disturbance. (2) The hemorrhage was profuse and continuous. It had persisted for four years in spite of repeated attempts by various means to control it. (3) The hematuria was unilateral. (4) Repeated examination of the urine failed to show any evidence of nephritis. The presence of albumin in the urine was accounted for by the blood present. No casts were ever found. There was never an interval when the urine was free from blood. (5) On exploring the kidney it appeared normal except for the markedly granular appearance of the surface. Nothing was found microscopically to explain the hemorrhage. The operation was followed by an immediate cessation of the hematuria. Convalescence was rapid. The patient's general condition improved. (6) Histological examination of the kidney showed a chronic interstitial nephritis of a moderately severe grade, in which the hemorrhagic tendency was well marked. Albarran divided the nephritic hematurias into three clinical groups, as follows: (1) The hematuria appears along with other unmistakable symptoms of nephritis. (2) The hematuria precedes the evolution of nephritis possibly for years. After a longer or shorter period other signs of nephritis appear. (3) Hematuria is the only symptom. It is spontaneous, without apparent cause and is not modified by exercise or repose. The patient goes about his work as if nothing were wrong for days, months, or years.

4. **Infantile Malnutrition.**—C. H. Dunn points out that the majority of cases of the clinically indigestion type of malnutrition are due to a simple intolerance of fat or casein, and that the undigested fat or casein acts simply as an irritant, and produces malnutrition simply through deficiency of absorbed nourishment. There is no evidence, in this type of case, of any more far-reaching food injuries exerting a toxic influence on metabolism. The cause in this indigestion type is equally likely to be fat or casein; if the former, a low fat and high proteid is the proper treatment; if the latter, a split proteid. There are probably cases of severe intolerance of both fat and casein, which can only be successfully treated by breast milk. The examination of the stools for fat or casein is a means of diagnosis of the greatest possible value in this type of case, enabling the physician to direct the treatment properly from the start. This type of chronic intestinal indigestion is common in actual practice.

4. **Milk-Free Treatment of Typhoid Fever.**—W. N. Johnson and C. C. Watt report their results in the treatment of sixty-five cases of typhoid fever during the recent epidemic at Germantown, Pa. The dietetic treatment, on which the greatest reliance was placed for the results obtained, and which in the author's opinion was responsible for the very low percentage of cases with diarrhea, distention, and hemorrhages, and for the absence of perforations, consisted of broths, soups, gruels, gelatin, eggs, sugar of milk, and butter. Milk was absolutely eliminated, except in the convalescent stage. Great reliance was placed on gelatin, which was given almost *ad libitum*. According to Kemp, the ingestion of 7.5 per cent. of the total heat requirement of the organism in the form of gelatin spares twenty-three per cent. of the body's proteid. There is a total of 2,800 calories required by a man of 154 pounds weight (Chittenden); 210 calories in gelatin are necessary (one gram of gelatin contains 4.1 calories), so about fifty grams of gelatin, or about 1.5 ounce, are necessary. This amount in one quart of water gives a five per cent. solution, and can be flavored with lemon, vanilla, orange, or sherry, and sweetened with sugar of milk, and be given in divided doses during the day—between other feedings. Gelatin lessens the tendency to hemorrhage, in the author's opinion, and was largely accountable for the freedom in these cases from this serious complication. If venous thrombosis occurs, gelatin should be stopped. The gruels (barley, rice, and oatmeal) may be made of different

consistency. It is well to begin with a thin gruel (strained) and note the effect, and gradually thicken it if well borne. There were only four deaths in this series of cases.

5. **Pulmonary Tuberculosis and Peripheral Nervous System.**—J. L. Pomeroy notes that symptoms from disturbance of the peripheral nervous system occur not infrequently in pulmonary tuberculosis. The clinical picture presented is often confusing and at times of misleading diagnostic nature. It does not seem to be generally understood that even at the earliest one may find as a part of the symptomatology of this disease disturbances in the nervous system simulating rheumatism, neuralgia, or myalgia. There may be shoulder joint pain; or pain in the arms, on the chest, in the abdomen, in the back, or in other parts of the body. Schmidt, in 1899, described a peculiar painful area under the clavicle over the affected apex. This was to be demonstrated by pressing the finger tips down into the supraclavicular space. He called this *unilateraler Plexus Druck Schmerz*, and found it a quite constant sign or symptom in early tuberculosis. He attributed this symptom to adhesive inflammation at the apex of the lung, which involved the brachial plexus. Herpes zoster is a frequent symptom of pulmonary disease. Erythema nodosum is not uncommon in pulmonary tuberculosis. Obstinate sciatica, painful back, occipital neuralgia, painful toes and heels, *morbus digiti* (dead finger) are among the many curious complications met with in the clinical course of pulmonary tuberculosis. Many of these cases show actual evidence of neuritis, absent or exaggerated knee jerks, a changed skin sensation, tenderness along the course of the nerves, and muscular changes.

3. **Melanotic Sarcoma.**—H. K. Gaskill reports a case of melanotic sarcoma rapidly developing from a pigmented mole of the left foot which had been treated as a wart and had been subjected to considerable irritation. After an operation for its removal metastases appeared at various points on the leg and later on the trunk as high as the third rib and there developed the cancerous cachexia, edema of legs, abdominal ascites and general emaciation. The patient succumbed about seven months after the operation; no autopsy was allowed. The author insists on the importance of viewing with suspicion cases of this type of melanotic nevi, irregular in outline, waxy, smooth, frequently only slightly elevated and of a dark purplish or black color, and emphasizes also the importance of extensive operative measures if these growths show a tendency to extend.

7. **A Sign in Chronic Appendicitis.**—C. D. Aaron calls attention to a diagnostic sign which he has found exceedingly valuable in deciding when and when not to recommend operation for chronic appendicitis. In many cases he has been able to induce a referred pain or distress in the epigastrium or left hypochondrium, or in the umbilical, left inguinal, or precordial region by a continuous firm pressure over the appendix at McBurney's point. Many patients on whom an appendectomy has been performed fully recover from their apparent digestive disturbance. The digestive symptoms are caused by an irritation of the nerves, which reflexly induce a perversion in the secretion of gastric juice. In view of the difficulty of diagnosis of cases of chronic appendicitis without frequent recurring attacks this symptom is of special value; moreover it will explain many cases of gastric and intestinal disease for which the appendix is responsible. McBurney's tender point may be found in many cases of appendicitis though not in all, and this referred pain on pressure is regarded as a valuable sign in the diagnosis of chronic appendicitis itself.

9. **Early Paresis.**—A. Gordon states that while the clinical picture of paresis is characteristic in its advanced stages, the same cannot be said of the early period of the disease. The beginnings are insidious and always progressive. The earliest psychic manifestation is the slow irregularly progressive dementia which is naturally first observed in cultured individuals. Memory is usually affected early in the disease. The patient shows defects in his work, mistakes in figures and in writing; with these there may be seen neglect of personal appearance and oddities in behavior and irregularity in habits. The character and disposition are changed. There may be apparent a neurasthenic depression or a hypermanic exaltation and perversion of the moral sense. The defective memory, attention, observation, judgment, and disposition constitute the most important psychic alterations in the early stage. There are three types of bodily manifestations that not infrequently announce the oncoming paresis—apoplectic and epileptic seizures and attacks of aphasia. Vertigo is another manifestation. Another early bodily symptom is pupillary inequality which the author considers almost pathognomonic. The characteristic speech and tremor are infrequent in the early stages. The author places special stress on the lymphocytosis in the cerebrospinal fluid, the Noguchi precipitation test and the Wassermann reaction. In case of cerebral syphilis there is more difficulty, but the character of the progressive dementia is different and the presence of headache and local symptoms often aid in the diagnosis. In chronic alcoholism and in lead-poisoning syndromes occur closely simulating paresis, but if the Wassermann and other tests mentioned are absent and the symptoms disappear after the withdrawal of alcohol the differentiation can usually be made. In lead encephalopathy the dementia seems to dominate the clinical picture from the outset.

13. **Cultivation of the Virus of Poliomyelitis.**—S. Flexner and H. Noguchi report that they have succeeded in cultivating on artificial media the virus of infantile paralysis. They employed for their experiments tissues from the brain and spinal cord of human beings who died of epidemic poliomyelitis, and of monkeys the subjects of the experimental disease. Part of the tissues had been preserved for many months in 50 per cent. glycerin solution and were free from ordinary bacterial contamination, as were the fresh tissues. The cultivations were conducted both with Berkefeld filtrates and tissues in substance. The culture mediums consist, first, of sterile, unfiltered ascitic fluid or of brain extract to which fragments of sterile rabbit kidney and a layer of paraffin oil have been added, and of these plus 2 per cent. nutrient agar-agar in proportions of 1 to 2. The first mediums permit of a slow growth not visible to the naked eye, while the second (which are unsuitable for obtaining the initial growth) yield, after several days, visible minute colonies clouding the tubes. The cultivations are conducted under anaërobic conditions, and the colonies do not ascend to the summit of the deep

layer of solid medium. The minute colonies are composed of globular or globoid bodies, averaging in young cultures 0.15 to 0.3 micron in size. The bodies appear in a variety of arrangements: single, double, short chains and masses. Often they appear embedded in a material of different refractive index. In older cultures certain bizarre forms have been noted. The cultivated bodies stain a pale reddish violet in Giemsa's solution, and bodies of identical appearance have been demonstrated by Noguchi, also with Giemsa's solution, by a specially devised method in films prepared directly from the nervous tissues. Monkeys have been inoculated with the cultures. Two series of inoculations have been made and a third series is in progress. Cultures from human tissues in the third, and from monkey tissues in the fifth generation have caused typical experimental poliomyelitis in the monkey. The findings at autopsy and the microscopic appearances of sections of the spinal cord, medulla, and intervertebral ganglia were characteristic of the disease. From the nervous tissues of these animals other monkeys were successfully inoculated and pure cultures recovered.

**Treatment of Inoperable Cancer.**—Sir Alfred Pearce Gould discusses this subject under the two headings: (1) the general treatment of cases of inoperable cancer, and (2) the special treatment of cancer other than by operation for its removal. In the general treatment the importance of physical and mental rest is emphasized. Strict cleanliness must be observed. The diet should be simple, easily digestible, and varied. Alcoholic stimulants of all kinds are to be avoided. The regular action of the bowels must be attended to. The following palliative operations are referred to: Gastronomy is a most valuable procedure in cases of malignant stenosis of the gullet. In the case of irremovable cancer of the colon or rectum, colostomy is to be performed if there is marked obstruction, severe pain, or free hemorrhage. Cystostomy is sometimes of value in cancer of the bladder or prostate. Gastroenterostomy in cases of irremovable pyloric stenosis is generally attended with great benefit and notable prolongation of life. Neurectomy for the relief of severe pain in properly selected cases has a place in surgery. Diathermic coagulation as a means of removing sloughing and ulcerating growths without pain and without hemorrhage is superior to all forms of curettage or cauterization. Among the non-operative measures the author speaks first of the *x*-rays. By the use of these in cancer of the breast he has seen foul ulcers cleaned, and some of them have healed up entirely. The following cases are reported by the author as having responded favorably to the action of radium: adenocarcinoma of the abdominal wall, malignant growth of the superior maxilla, tumor of the parotid gland, sarcoma of the femur, and a malignant growth in the right groin.

2. **The Etiology of Endemic Goiter.**—R. McCarrison concludes that thyroid enlargement can be experimentally produced in man within a few weeks by the administration of the suspended matter separated by filtration from goiter producing waters. Thyroid enlargement cannot be so produced when the suspended matter is boiled. The goiter produced in this way must almost certainly be due, not to the mineral but to the living component of the suspended matter. While it cannot be said to be definitely proved by these experiments that filtration through a Berkefeld filter wholly deprives the water of its goiter-producing properties, water so treated does not appear to be capable of causing goiter in man within a period of fifty-five days. The results of these experiments and the observations the author has already quoted indicate that the living excitant of goiter exists in greatest abundance in the deposit at the bottom and sides of water-channels, tanks, wells, and other receptacles of goiter-producing water. The following are the characteristics exhibited by experimentally produced goiter in men: (1) It usually appears about the fifteenth day of the experiment. (2) It shows a marked tendency to fluctuate in size. (3) It reaches its point of maximum size between the twenty-fifth and thirtieth day of the experiment. (4) The enlargement of the gland is not great, nor is it progressive under the conditions of the experiment. (5) It is accompanied, as a rule, with certain subjective symptoms of throbbing in the neck and feelings of fulness and discomfort. (6) It may completely disappear under the conditions of the experiment. Soil is also a vehicle of the living contagion of goiter. Limestone and lime-bearing rocks are most commonly associated with the disease. These porous rocks form the normal habitat of the organic substances that cause the disease. What, then, the author asks, are the ideal conditions for the development of goiter? They are to be found in a country district with an agricultural population living on a porous soil, which soil contains much organic matter and by virtue of its porosity or slope admits of the ready passage of organic matter into the unprotected streams and wells that are the water-supply of the people. It is in mountainous countries where limestone rocks abound that these conditions are most frequently found in combination. Consequently, goiter is pre-eminently a disease of the hills, and its relationship to the soil is clear.

7. **Pathogenicity and Virulence of Bacteria.**—F. H. Thiele and D. Embleton have found as the result of their investigations that ferments form an important normal mechanism of defence against bacterial invasion. The ferments performing this important function are: (*a*) the normal panenzyme, (*b*) the slightly differentiated specific enzyme, (*c*) the thermolabile specific coenzyme or amboceptor, and (*d*) the thermostable specific coenzyme or amboceptor. These last two supplement and accelerate the action of the ordinary enzyme. The action of the ferment is to bring about proteolytic digestion of the bacteria. Exotoxins and endotoxins are bacterial protoplasm and are not primarily toxic *per se*, but only become so when acted upon by the ferments. The action of the ferments on the bacterial protoplasm is to produce toxic early proteolytic digestion bodies. These bodies, besides being toxic to the animal, are also aggressive in the sense of Bail—*i. e.* are antiphagocytic. The action of this toxic substance, besides being aggressive, is to produce (*a*) in large amounts, death; (*b*) in lesser amounts, fall of temperature; and (*c*) in small amounts, fever. This substance is the cause of death in all bacterial infections. The virulence of a bacterium is dependent upon the power of exuding around itself a zone of its cytoplasm, which remains in position and acts as a protective shield. The production of a zone of ferment equilibrium in this shield protects the bacterium itself from the penetration of the ferment. The shield thus acted upon is also aggressive to phagocytosis. Pathogenicity is due to (*a*) the virulence of the bacterium, and (*b*) the relative activity of the ferment to the bacterium. Thus, the authors hold, one should say that immunity is due to the ferment action and phagocytosis—*i. e.* it is cellulohumoral.

1. A Report of the Work Carried Out at the Radium Institute From August 14, 1911, to December 31, 1912. A. E. Howard Pinch. Appendix Report of the Chemicophysical Laboratory. W. L. S. Alton.
2. The Diagnosis and Treatment of Cancer of the Rectum. W. E. Miles.

1. **Report of the Radium Institute.**—A. E. Hayward Pinch describes the various forms of apparatus employed at the Radium Institute of London, these forms including flat varnished applicators, capillary glass tubes filled with radium sulphate, and radium emanation collected in glass tubes or dissolved in distilled water or weak saline solution. The screens employed as filters for the different rays consist of aluminum, silver, or lead. Very different results are obtained with epitheliomata affecting the glabrous skin as opposed to those involving mucous surfaces. Epitheliomata of the face, trunk, or extremities, if flat and superficial and accompanied by little or no ulceration, give satisfactory results when treated with quarter or half strength apparatus, screened with 0.2 mm. of lead, the exposures varying from six to twelve hours' duration, spread over a period of three or four days. The retrogression of the growth is quickly brought about and little or no scarring results. Ulcerating epitheliomata without much adjacent infiltration, require treatment with quarter or half strength apparatus applied unscreened for a total exposure of two to six or eight hours, spread over a period of four or five days, and repeated after an interval of six weeks if necessary. A destructive reaction follows, but the result is usually quite good, and there is but little cicatricial contraction. Ulcerated epitheliomata with great infiltration require prolonged treatment with heavily screened apparatus emitting "ultra-penetrating" rays. Exposures of thirty to sixty hours given during one week, and repeated in five or six weeks' time are best; but if the growth shows signs of rapid extension the borders should be given a vigorous treatment with unscreened apparatus. Epitheliomata of the tongue and of the buccal, gingival, and pharyngeal mucous membranes are almost uniformly disappointing in their ultimate response to radium therapy. Temporary improvement is not infrequently seen, and this sometimes goes as far as disappearance of the original lesion; but the treatment has practically no effect in preventing or delaying the appearance of metastatic deposits in the cervical glands and elsewhere. The rate of growth of the infected glands can often be retarded by the prolonged and persistent use of the "ultra-penetrating" rays. If the dose given be a large one, the glands sometimes break down and discharge a milky-white fluid through a small sinus, and it is remarkable that ulceration of glands thus treated rarely occurs. Considerable difficulty is experienced in giving satisfactory exposures within the oral cavity, as patients are often unable to tolerate the presence of applicators in their mouth for the necessary length of time, and should the reaction be at all pronounced the congestion of the tissues occasions great discomfort. There is the further danger that a severe reaction may act as a stimulus to the original growth, increase its size, and hasten metatasis.

In cases of inoperable malignant disease of the uterus radium will often bring about results which cannot be attained by any other known method of treatment. The hemorrhage is arrested, the discharge is diminished in amount and rendered inoffensive in character, the ulceration is healed, and the pain is greatly relieved. The rate of growth is checked, sometimes completely arrested, and the surrounding infiltration and induration are so much lessened that in a few instances cases previously declared to be inoperable become operable. The treatment is best carried out by the introduction of a tube containing 50 to 100 mg. of radium, screened with 2 mm. of lead and 3 mm. of rubber into the cervical canal, or, if this be not practicable, into the posterior fornix, a large flat strong applicator screened with 2 mm. of lead being placed on the abdominal wall over the fundus of the uterus. The exposures should be prolonged, and should be from thirty to sixty hours' duration, spread over a period of from five to ten days. The series of exposures should be repeated at intervals of not less than six weeks. The action of radium is, however, only local, and though it may, and often does, check the rate of growth, yet in most cases dissemination will sooner or later occur, and the disease spread to parts beyond the effective range of radium. In carcinoma of the rectum and of other parts of the lower alimentary tract, radium therapy not infrequently proves of considerable value, but it is extremely difficult to say what are the factors which determine or contribute to the success of the treatment. Speaking in general terms, the application of radium results in the arrest of hemorrhage, the healing, partial or complete, of any ulcerated surface, a diminution of the amount of the discharge, less pain, and a retardation of the rate of progress. In some instances more striking changes manifest themselves. The growth shrinks in size, undergoes a fibrous transformation, and becomes much less fixed to the underlying tissues, so that a carcinoma which before radium treatment was regarded as inoperable can be easily and completely removed. A few patients manifest an unusual degree of susceptibility to radium when applied within the rectum, and a relatively short treatment of eighteen to twenty-four hours with heavily screened radium is followed by a severe though transient proctitis. The routine method of treatment in rectal cases is the introduction, through an operating sigmoidoscope, if necessary, of 50 to 100 mg. of radium screened in 2 mm. of lead and 3 mm. of rubber. It is maintained in position by a stem of soft silver wire, which is bent at an acute angle at the anal orifice, and fastened by strapping and a T bandage in the fold between the buttocks. Each exposure is from six to twelve hours in duration, and is repeated daily until a total treatment of thirty to sixty hours has been given. The series should be repeated after an interval of six weeks.

The results of radium therapy in the treatment of cancer of the breast are, on the whole, encouraging, and this is especially the case when the primary growth is of the sclerotic rather than of the medullary type, when the secondary deposits occur in the skin lymphatics and lymphatic glands, and there are no internal metastases. Radium should never be used as a substitute for operative interference, but when the case is inoperable it will do much to relieve pain, promote the healing of ulcerated surfaces and check the growth of the secondary deposits. In not a few cases it will bring about the almost complete absorption of superficial carcinomatous nodules and infected glands. Instances have been noted in which the physical signs were strongly suggestive, if not positively indicative, of carcinomatous deposits in the lungs, and the prolonged application of from thirty to forty hours of a large quantity of radium screened through 2 mm. of lead has brought about an apparent resolution. In rapidly growing cancers of the encephaloid type radium can do little but relieve pain. The postoperative lymphatic engorgement of the arm on the affected side is sometimes distinctly benefited by the application of a heavily screened tube of 50 to 100 mg. of radium placed at the apex of the axillary cavity, an exposure of twenty-four to thirty hours spread over five days being given. Rodent ulcers constitute of all forms of malignant disease the one which is most amenable to the action of radium. Untreated rodent ulcers not exceeding 2 cm. in diameter, and not affecting mucous membrane, cartilage, or bone, almost invariably yield to one exposure of one to three hours' duration with a full strength applicator unscreened.

**Nystagmus in Febrile Diseases.**—Von Czyhlarz investigated a series of febrile affections for the presence or absence of nystagmus. While the research was in progress Beck and Biach published a monograph on the same subject, their work having been done under Professor Chvostek. The results in the two series of observations show an essential agreement. There can be no doubt that febrile nystagmus is of frequent occurrence. But while the other Vienna men found nystagmus absent in tuberculosis (except the miliary form) and typhus, the author found that there was nystagmus late in the course of typhoid, and persisting well into convalescence. He also found the phenomenon in ordinary pulmonary consumption with high temperatures, but it is much less common than one would be led to expect. Nystagmus appears to be especially common in fevers which come on suddenly—erysipelas, influenza, pneumonia, articular rheumatism. The febrile type appears to stand in some relation with a toxic type, noted, for example, in acute cinchonism and acute alcoholism; and is itself doubtless of toxic origin.

**Blood Finds in Tuberculosis**—Rabinowitsch discusses fully the subject of the paradoxical occurrence of tubercle bacilli in the blood of subjects of all kinds, including the apparently healthy. She traces the subject historically, even as far back as Virchow's time, when in 1891 he discussed the mobilization of bacilli in old foci, which could lead to a bacillemia. This mobilization was attributed to the action of tuberculin. Studies of blood after injection of tuberculin seemed to antagonize Virchow's belief. Naturally the occurrence of bacilli in the blood in general miliary tuberculosis was never at any time in dispute, because it furnished the sole rationale of that affection. Only in quite recent years has the claim been made that the bacilli may often be found in the blood of known tuberculous and other subjects without any apparent clinical significance. Some Japanese investigators have asserted that bacilli are present in the blood of any individual who gives a positive von Pirquet reaction. The discovery of the bacilli in the blood of subjects who may actually be pronounced free from tuberculosis has naturally plunged the entire subject into a temporary chaos.

**Unilateral or Bilateral Strumectomy?**—Tietze's unilateral operation is a total extirpation, while his bilateral procedure is a bilateral resection. Comparing both series of operations in his own clinic with each other and with the results of other operators he concludes that unilateral extirpation is the smoother procedure in every way from the technical viewpoint. The parathyroid and recurrent nerve of the operated side need not be compromised. Hence whenever one side is chiefly involved, the indication for unilateral extirpation is clearly present, the isthmus being divided. Bilateral resection, however, has a field in diffuse bilateral goiter, wedge-shaped pieces being excised and the organ then sutured. The lower poles and the isthmus are left intact.

*January* 21, 1913.

**Botulism.**—Schumache reports an episode of botulism attacking six persons, the *Bacillus botulinus* having been successfully demonstrated as the cause. A man and wife were taken with colic in the night, but went to their work as usual. They were soon compelled to return home on account of prostration and vertigo. The colic had not led up to diarrhea or vomiting. Dysphagia next set in with hoarseness and dyspnea. During the first day there also developed bilateral ptosis, which was the forerunner of numerous other eye symptoms—mydriasis, diplopia, paralysis of accommodation. There was persistent constipation with retention of urine. One physician diagnosticated diphtheria by reason of the associated hoarseness and dyspnea, and complete inability to swallow. These symptoms were, in fact, the threatening part of the disease. There was no constitutional reaction in the ordinary sense, as temperature and pulse were normal throughout. Pilocarpin gave some temporary relief. The man died on the sixth day with clear sensorium. Autopsy within 24 hours showed marked congestion of the internal organs, fluid state of blood, and edema of lungs, which last had apparently caused death. Diphtheroid membrane was present in the throat. The mother of the patient died a similar death, having presented paralysis of deglutition and speech disturbances. The patient's wife, already mentioned, recovered after having presented the same train of symptoms. She was left with speech disturbances and slight paresis of the right hand. Three children of the family were ill, but recovered. The author now proceeds to establish the nature of the malady, which was clearly one of wholesale poisoning, or infection. Rabies was first readily excluded, as was mushroom poisoning; poisoning by the atropin group and by hemlock (sometimes mistaken for parsley) could also be excluded. Diphtheria had been thought of only in connection with the first victim because of the paralysis of the eye and throat. But one condition remained for consideration, to wit, botulism. All had eaten of raw ham which had a bad odor and taste, and had on that account been given to the dog. Four members of the family who did not partake of this ham escaped the disease. Further, some of the ham had been cooked and eaten by one child who had not touched the raw ham. She remained well. One child may have owed his life to his school teacher who had told him never to eat ill-smelling meat. The dog, who ate between one and two pounds of the raw ham, was but slightly indisposed. Some of the meat remained and was variously tested. A filtered infusion poisoned mice without fail when simply eaten. Search was now made for bacilli and the *B. botulinus* was obtained in pure culture. In theory this affection should be amenable to serum therapy, as it represents a pure toxicosis like diphtheria and tetanus, a fact which has long been recognized.

**The Hypophysis and Diabetes Insipidus.**—Simmonds relates a case history which shows beyond doubt that a lesion of the hypophysis can produce persistent polyuria. The organ, now known to possess three, instead of two separate portions, exerts an unusual variety of functions. Only the anterior portion is concerned with skeletal growth. The posterior lobe, long believed to be inert, was eventually brought in relationship with metabolism and the genital glands. Finally, the third, or middle lobe, or interlobular portion, first isolated by Schäfer, stands in definite relationship with the renal blood vessels and cells. While acromegaly and adiposogenital dystrophy have been sometimes accompanied by diabetes insipidus, the present case seems to be the first isolated example of the latter and was evidently determined by a cancerous metastasis.

---

### Deutsche medizinische Wochenschrift.

*January* 9 *and* 16, 1913.

**Calcium Metastases and Calcium Gout.**—Schmidt concludes that calcium overloading of the blood may alone lead to deposits in the sound tissues. This has been shown by Tanaka's researches and many forms of human calcium metastases in skeletal disease (without presence of nephritis). There also occur metastases without skeletal absorption, but in these as in the majority of all cases one expects to find the nephritic component. In cases without nephritis and without skeletal disease one is forced to

assume not the existence of a primary tissue dyscrasia but an altered solubility of calcium in the blood just such, in fact, as occurs secondarily in kidney disease. In classic cases with both osseous and nephritic participation the author believes that the chief factor still lies in the altered solubility, the other factors being only contributory. In most cases of primary nephritis and bone disease one does not see calcium gout. While the tissues in which the metastases occur do not appear to be the seat of any primary dystrophy, there are other elements of predisposition—some organs are physiologically predisposed, as the lungs, gastric mucosa, kidneys, blood-vessels, etc. It is conceivable that in pathologic states such predisposition will be increased.

**Protozoa Finds in Swimmers' Conjunctivitis.**—Huntemüller and Paderstein report numerous finds of Chlamydozoa—an alleged cause of trachoma, in the discharges of patients with so-called "swimming tank conjunctivitis." In not all cases was there a history of exposure in these public tanks, but the resemblance was unmistakable. In most cases the clinical picture was one of acute trachoma, and there was a history of use of the public tanks very shortly before the lesions appeared. This condition was first noted many years ago, and the cumulative or pseudoepidemic incidence was set down purely to ordinary trachoma. The series of cases now described by the authors show the same cumulation of incidence and trachomatous picture and the same history of the swimming tank exposure. But the first of these tank epidemics (about 1899) was found after following up the cases to be a relatively harmless affair. The so-called trachoma bodies had not then been described. Now the first step was naturally a search for them. This the authors instituted thoroughly, including inoculation experiments on monkeys. It was decided that the finds very closely resemble those of manifest trachoma. Yet in view of the mild clinical course one cannot determine whether swimming tank conjunctivitis is a mitigated trachoma or simply a mild affection belonging to a common family group.

**Nongonorrheic Ophthalmia of the Newly Born.**—Credé-Hörder describes this affection as follows: The eyelids adhere; the palpebral fissure and continuous surfaces are reddened; the upper eyelids are moderately swollen; the secretion is purulent or seropurulent; conjunctiva as a whole is injected; cornea clear. Hence we see here no difference whatever from a beginning gonococcic conjunctivitis of good prognosis. The microscope, however, shows no gonococci but instead some other pathogenic germ or germs—Gram positive diplococci, pneumococci, or the colon bacillus. Since conjunctivitis from these causes is long known, the chief lesson to be learned refers to their incidence at birth and the obligation of an accurate diagnosis in all cases. For all these conditions are relatively harmless and furthermore their presence carries with it no stigma.

**Present Status of Functional Renal Diagnosis.**—Henius briefly sums up the methods of diagnosis now in vogue. Authors differ considerably in regard to the determination of urea and the chlorides. Some hold this to be relatively unimportant, or as giving only untrustworthy results. With such differences of opinion as to essentials we may pass on to cryoscopy, in which field, however, we find precisely the same discord—one school regarding it as practicable and valuable, the other as worthless, with intermediate shades of opinion. The third resource—elimination of coloring matters, including chromocystoscopy—has the support under one form or another of the majority of specialists, but Rovsing, who is one of the leading advocates of ureametry as a resource pronounces it of no value at all, while Casper, a champion of cryoscopy, is lukewarm as to its usefulness. The phloridzin test has partisans and enemies. The most recently introduced test—phenolsulphonephthalein—seems thus far to have only a few adherents. The other resources in use need not, Henius says, even be enumerated. The author sums up his general review of the subject by stating that our knowledge in this province is only in its initial stages.

**Prostatic Elements in Urethrorrhea ex Libidine.**—Pfister refers to the slight ropy discharge from the urethra which follows erections of the penis and was once believed therefore to be dependent in some way on pressure differences resulting from expansion of the collapsed urethra, or else is a necessary step in rendering viable the spermatozoa. The fact, however, that the phenomenon occurs in the absence of erection—especially in old men—in the presence of subjective sexual excitement, led to the introduction of the term urethrorrhea ex libidine. The old belief that the secretion is of prostatic origin seemed to have been disproved by extended microscopic studies. Pfister, however, finds prostatic elements present, at least in certain cases. A well preserved man of 62, who became sexually excited in the presence of newly made female acquaintances, suffered from a urethral discharge, which contained as formed elements only corpora amylacea from the prostate. The latter organ was found to be normal, and defecation spermatorrhea was readily excluded. The discharge, from its mucous component and negative character, was evidently from Cowper's and Littré's glands. The problem was how to account for the presence of the corpora amylacea without other formed elements from the prostate. The most plausible supposition was that these had entered the prostatic urethra directly, not through the prostatic ducts, or at least only at the exits of the latter. The association was therefore fortuitous—two conditions existing side by side, to wit: the urethrorrhea ex libidine and atony of the prostate. The coexistence of these two conditions, in men of advancing years, Pfister says, has been remarked by Markuse.

**Hemicanities in Hemiplegia.**—Loeb relates an interesting case of this association which, however, can only be classed as freakish behavior. Graying of the hair, moustache, etc., of one-half of the head and face after a paralytic stroke is so extremely infrequent that no significance can be attached to it, save as a document to the belief that sudden graying is possible, which many deny. From this and a few other observations some light may possibly be shed on sudden blanching of the hair, not only *en masse* but in patches, the latter phenomenon being not so rare.

---

**Acute Vascular Lesions Produced by Pneumococci.**—T. P. Sprunt and J. A. Luetscher note that mice dying several days after injections of pneumococci, both living and dead, frequently show at autopsy large intrathoracic hemorrhages. The histological study of the thoracic organs indicates that there occurs in each case a sharply circumscribed, acute degeneration of the wall of some large vessel, usually the ascending aorta or one of the pulmonary arteries. This degenerated portion is torn out by the pressure of the blood with an almost complete disappearance of the vessel wall, leading to a gross hemorrhage. A similar change is occasionally found in the walls of the veins which contain cardiac instead of smooth muscle. The authors have found this lesion only in mice which had been recently inoculated with pneumococci. Negative cultures at autopsy, the lack of inflammatory reaction, and the occurrence of the conditions after injection of dead pneumococci suggest that the cause may not improbably be a toxic degeneration of the vessel wall brought about by the poisons of the injected organisms.—*Journal of Experimental Medicine.*

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### THE INSURABLE INTEREST.

The question of the insurable interest of the beneficiary is one which is usually worked out between the company, the agent and the applicant. When, however, circumstances appear in the case which create doubt or arouse suspicion, the examiner will usually be in a position to assist the company in clearing up the matter through his familiarity with the characteristic traits, habits, conditions of life and general surroundings of the applicant.

A contract for life insurance should be supported by a legal insurable interest which means that the beneficiary should have a lawful interest in the continuance of the life of the insured and not merely a monetary or speculative interest in the event of his death. The beneficiary should be dependent on the insured for support, or the insured should be indebted to the beneficiary for an amount sufficient to justify the sum insured, or the beneficiary should have some other substantial interest in the life of the insured. A satisfactory explanation should be called for whenever these requirements are not clearly and properly fulfilled.

The most common departures from the course of legitimate insurable interest may be divided into the following classes:

*Insurance on Wives in Favor of Husbands.*—An innate prejudice exists against the man who permits insurance to be issued on the life of his wife for his benefit except under certain circumstances. The husband usually regards himself as the provider for and the protector of his family, and the idea of any profit accruing to him through her death is repugnant even to the extent of being reimbursed for the necessary expenses of her sickness and burial. The reluctance of the companies to writ policies with the husband as beneficiary is not, however, entirely due to this sentiment; it is based upon significant statistics which show that the mortality among women insured in favor of their husbands, as a class, is greater than that among insured single self-supporting women, or women who took out insurance before marriage. It is suspected by many insurance men that some of this increased mortality is due to occasional absence of that care and protection which every husband should throw about his wife during illness, and that anxiety over the possibility of her death is softened in such cases by the prospects of the monetary compensation to come.

On the other hand, insurance on the wife's life may be quite legitimate and beyond criticism, and the companies are ready to issue policies as soon as this fact is made clear. These exceptions may be described as follows:

(a) A woman may be the beneficiary of an estate in trust, the income of which goes to some other person than the husband at her death. This income may be ample to allow comforts and luxury, and it is quite proper under such conditions for her to provide some means by which the husband can continue the same way of living in case of her prior death.

(b) A woman may have a separate and distinct income of her own and possess the desire to make the burden of her husband as light as possible. The husband will not have to pay the premiums and does not necessarily take any part in the transaction. The company should take steps to convince itself that the wife has the means to pay for the insurance.

(c) The husband may be an invalid and the wife anxious to provide for his support, if she should die first though in good health when the policy is issued. The wife in such a case is the provider to some extent, if not entirely so, and there will usually be no objection to the issuance of the policy unless the husband is afflicted with tuberculosis or some other infectious disease.

(d) The husband and wife may be partners in a business in which the death of either one would leave the survivor without the assistance of certain skill and ability of the partner or financial aid. Joint insurance on husband and wife has been found to be unprofitable, but there will be no hesitation on the part of the company to issuing individual insurance to either one or both with the wife or husband as beneficiaries, provided the inspection and commercial reports are favorable.

*Insurance on Minors in Favor of Parents.*—Insurance on minors is usually encouraged by the parents with the idea of teaching them the importance of saving and thrift. Enthusiasm on the part of the officers of the company in approving insurance for the purpose is, however, dampened when the beneficiary named in the application is the father or mother who will also pay the premium. It can not be forgotten that minors, even when they arrive at the ages of from 15 to 20, are still under the care and protection of their parents and depend upon them in the case of illness or accident, and insurance on such conditions is not altogether based on good principles. No company should write such a policy until it has instituted strict inquiries into the character and circumstances of the family.

The minimum age at which insurance will be written is usually placed at 15 years in order to prevent speculation as far as possible. When the minor is self-supporting and pays the premium, the question of speculation is practically removed.

*Insurance on Parents in Favor of Self-Supporting Children.*—If a man or woman of fairly advanced age is able to and intends to pay the premium, there is no special reason for refusing insurance, provided the age limit, which varies from 60 to 70 in the different companies, has not been passed. It should be kept in mind, however, that the premiums for ages above 60 are necessarily high, and that a careful inquiry as to the motives for paying so large an amount and the financial condition of such applicants is quite necessary.

Unfortunately, a great many men and women in advanced years of life have allowed themselves to be used as objects for speculation by selfish and unnatural children or designing sons-in-law who have paid the premiums themselves. When further explanations and a searching inspection establish this intention to speculation, or an inability of the applicant to pay the premium, the risk should be summarily rejected.

*Corporation Insurance.*—This form of life insurance is becoming more popular and calls for policies of large amount. There has been doubt in some quarters as to the wisdom of accepting these impersonal risks, but the experience of the largest and best advised companies has demonstrated that business of this character is legitimate and profitable if the inspection and commercial reports are entirely favorable.

The insurance is usually taken out on the life of some individual connected with the corporation,

whose ability, skill or influence is so valuable an asset that the welfare of the concern largely depends upon it. His value may be in the form of specialist in that particular line of manufacturing or business, inventor, originator, or in his executive ability. Capital has been invested in the enterprise chiefly on the strength of this man's unusually important services and would suffer in the event of his death.

In considering the issuance of insurance for this purpose, the companies must secure convincing proof in regard to the responsibility of the corporation, the soundness of its financial condition, the character of its officers and promoters, and the actual value of the insured to the concern.

---

**Diabetes Mellitus and Life Insurance Examinations.**—F. Parkes Weber states that it is well known that not every case in which sugar is discovered in the urine should be refused for life insurance. He refers to the possibility of the temporary absence of sugar from the urine of diabetic patients, when undergoing medical treatment, becoming a source of serious error from the insurance point of view. Every one knows that in slight cases the sugar in the urine may be got rid of by suitable diet; and the use of certain drugs, such as aspirin and calcium iodide, has been said occasionally to have a similar effect. But it is not quite so generally well known that in grave cases of diabetes mellitus, in which sugar cannot be completely got rid of by ordinary dietetic methods, it may occasionally be temporarily banished by the employment for a day or two of (more or less disguised) starvation methods. Thus, in a young woman, aged 23 years, under the author's care in 1909 at the German Hospital of London, the sugar in the urine was reduced by careful dieting to about 70 grams for the twenty-four hours. On September 10 the diet was temporarily limited to 200 to 300 grams of olive oil in the day, with as much water as was wished for, and a codeine phosphate pill (which the patient had been taking three times a day) was continued. As a result of this disguised sarvation method sugar completely disappeared from the urine on September 12, and on September 13 the author ordered a return to the special diet for her diabetes. On the next day the urine contained 4.5 per cent. sugar again. During the days of exclusive olive oil diet the patient did not feel hungry or as if she was being starved. Once or twice she felt a little nausea, owing to the oil, but she looked well and had her usual somewhat florid complexion. She lost only about 4 pounds in body weight. She was not emaciated, and on the whole gained weight while she was in the hospital. This case was one of grave diabetes mellitus, but surely a life insurance examiner, had he examined her when the sugar disappeared, might have been deceived. The reaction for diacetic acid was indeed positive, but in the absence of sugar the examiner would hardly have tested the urine for diacetic acid. Other "hunger cures" or "starvation cures" can similarly temporarily remove the glycosuria. Thus, at the Edinburgh Medico-Chirurgical Society, December 15, 1909, F. D. Boyd brought forward a case of severe diabetes mellitus in which a single "hunger day" caused complete disappearance of glycosuria for twenty-four hours, the sugar reappearing afterwards in only small amount. G. Guelpa of Paris refers to the case of a man who was refused for life insurance on account of diabetes. The result of Guelpa's treatment by starvation and purgation was that on the evening of the second day of treatment the urine no longer reduced Fehling's solution. On the third day the man presented himself for a life insurance examination, and no obstacle to his acceptance could be found. In grave cases sugar may sometimes vanish from the urine on a trial of von Noorden's "oatmeal diet."—*British Medical Journal,* January 11, 1913.

**Albuminurics in Relation to Life Insurance.**—Dr. Soot Skirving, in a paper presented before the New South Wales branch of the British Medical Association, speaks of the attitude taken by him as Medical Referee toward applicants whose urine examinations showed albuminuria in varying degrees. Insurance societies, until recently, have looked somewhat askance on albuminurics in general, but he in his year's work has arrived at a distinction in these cases, dependable on several factors, such as age, previous condition of health, and family history.

These albuminuric cases are broadly divided into two classes—functional and organic. The factors determining functional and not organic albuminuria are as follows: (1) Absence of any recent cause for nephritis, such as the exanthemata, diphtheria, or a clear history of ordinary antecedent acute nephritis with its classical signs. (2) Absence of any of the ordinary stigmata of chronic renal disease, especially cardiovascular changes. (3) The fact that the proponent is under 25 and presents a healthy, wholesome appearance. (4) That the urine is of a good or even high specific gravity. (5) That the amount of albumin is very slight or moderate in amount—that it is not constant, *i.e.* that it is often absent at certain hours of the day, and frequently its appearance is influenced by food or by cold. (6) That the microscopical examination of the urine reveals no important suggestive abnormality. (7) That the blood pressure is not unduly high.

The impossibility of determining all these points in one urine examination of an albuminuric is realized, so three tests, about six hours apart, covering twelve hours, are made, and in frequent instances the urine is examined microscopically, and the blood pressure recorded.

If the above facts, taken generally, are favorable, and the applicant is under 25 years of age, he is accepted at the rate for age. If the applicant is over 25 and under 30, acceptance is advised at select rates or with moderate loading. Over 30, cases are often deferred or accepted with a heavier loading. As before mentioned, the family history, previous state of health, and age of the applicant have a strong bearing on the ultimate outcome of these cases. Each case must be judged on its own merits. In a synopsis of 156 cases presented, showing albuminuria, a little over 2 per cent. were women; 112 ranged from 16 to 25 years; 17 at 15 years or under, and 27 over 25 years.

Skirving, for all ordinary purposes, employs the time-honored Heller's cold nitric acid contact test, and Esbach's test, always remembering the possible presence of nucleo-albumin or urates. From the business or actuarial viewpoint, the admission of these functional albuminurics to the benefits of life insurance is advisable, as the greater majority turn out well. As to the financial success gained by the present attitude of the writer's company toward these cases, only time can show; but much evidently depends on the keenness of diagnosis of the medical examiner.—*Australasian Medical Gazette,* November 2, 1912.

# Book Reviews.

THE COURSE OF OPERATIVE SURGERY. A Handbook for Practitioners and Students. By Prof. Dr. VICTOR SCHMIEDEN, Privatdozent of Surgery in the University of Berlin, Assistant in the Royal Surgical University Clinic. With a Foreword by Prof. Dr. A. BIER. Second enlarged edition. Translated and edited by Arthur Turnbull, M.B. (Glasg.), M.A., B.Sc., Demonstrator of Anatomy in the University of Glasgow. Price $4.00 net. New York: William Wood and Company, 1912.

THIS volume represents more than the usual translation of a foreign work. The freedom from vague statements and relics of the German idiom indicates quite as well as his own statement the translator's entire familiarity with the actual performance of the operations described. To the American surgeon the book could not be and is not offered as a treatise on operative technique, but as a guide and handbook for students and practitioners taking a course in operative surgery in the laboratory it leaves little to be desired. The entire range of operative procedures is covered in a most complete and practical manner. There is no elaboration of methods or of details of technique, nor portrayal of unusual operations, and the directions are simple and explicit. Furthermore, much obsolete matter commonly found in such textbooks is most gratifyingly absent. The operations described are the simple standard ones, and represent the practice of Prof. Bier's clinic. While this is in some details at variance with American methods, the fundamental principles governing each operation are so well emphasized that objection can hardly be made. It is interesting to note in this connection that a surprisingly large number of the operations described are of American origin and are duly credited to their authors. The quality of the text is borne out and enhanced by the character of the illustrations. The 354 drawings and reproductions of photographs used to portray topographical anatomy and the details of technique or steps in the operations are uniformly good. One can not consider, however, that the inclusion of some 81 cuts of instruments, many of them of obsolete pattern, is a valuable addition to the book. In keeping with the excellence of its contents the book itself is thoroughly well made and printed and merits a wide acceptance.

PRACTICAL EUGENICS. By WILLIAM J ROBINSON, M.D., President American Society of Medical Sociology, etc. Price $0.50. New York: The Critic & Guide Co., 1912.

THE title of this book leads one to expect some exposition of how we may set about to improve the human race. In this, however, the book is disappointing, for the author limits himself to urging his belief in the dissemination of knowledge of the means for the prevention of conception, and of the use of venereal prophylactics. The author is very earnest, but throughout the book there is a certain coarse vein, and lack of appreciation for moral training and guiding ideals. This is to be regretted because the author takes a very sane view of the question of heredity, being quick to recognize the social and economic phases.

SLEEP AND THE SLEEPLESS. Simple Rules for Overcoming Insomnia. By JOSEPH COLLINS, M.D., Physician to the Neurological Institute of New York. Price $1. New York: Sturgis & Walton Co., 1912.

THIS work is written on popular lines, its aim being to aid those who are afflicted with sleeplessness to cure themselves, and accordingly ample information with regard to the means to be pursued to gain this end is given. It is essentially a book for the layman, and although founded upon the latest scientific knowledge and data, technical terms are avoided. Dr. Collins uses a direct and concise style of writing and his choice of language is, generally speaking, apt and well considered. In the first chapter, however, he makes a statement at the accuracy of which some would cavil. He says that old age comes upon us sooner than in the days of yore, whereas, it is the opinion of authorities that nowadays the span of life in a general way has lengthened and seems to be lengthening. Referring to the influence of the will over the mind and senses the author points out that the capacity to sleep can be acquired by effort in the same way as the capacity to think concretely or to run without getting out of breath. He also wisely draws attention to the fact that insomnia is a relative term. As in eating and exercise and many other actions which bear upon health the personal equation must be always considered and thus the amount of sleep that suffices for one individual would be in another productive of misery and a disorder of nutrition which might lead to disease. After emphasizing the point that a person's surroundings should be conducive to sleep, the treatment for the cure or, at least, the relief of insomnia is discussed. Dr. Collins pins much faith on baths and hydrotherapy of various kinds and indeed deals with the whole treatment of insomnia in a sufficiently thorough manner. The chapter on opiates and narcotics is especially well put and restrained. The book is peculiarly well adapted for the layman and is a pleasing mixture of science, history, quotation, literature and treatment.

STUDIES IN CANCER AND ALLIED SUBJECTS. Pathology. Conducted under the George Crocker Special Research Fund at Columbia University. Volume II. The Columbia University Press, New York, 1912.

FOUR volumes of studies in cancer are promised by the research workers of the George Crocker Fund: the first to contain a general report on the present status of cancer knowledge, the second to deal with pathology, the third with biology, surgery, biological chemistry and clinical pathology, and the fourth the anatomy. The second volume has now appeared, while the other three are said to be "in preparation." It consists of twenty-seven articles, the authors being Isaac Levin, M. J. Sittenfield, Robert A. Lambert, Frederic M. Hanes, Robert T. Frank and A. Unger. Levin and Sittenfield have worked mostly on animal cancer, studying its laws of growth, transmission and immunity in white rats. In additional articles Levin discusses etiology of human cancer, cancer among the American Indians, the hormone theory of the causation of cancer, etc. Lambert and Hanes have grown "in vitro" pieces of transplantable animal tumor and have studied the conditions of such growth and the possible light it may throw on cell life in general. Frank and Unger present an experimental study of the causes which produce the growth of the mammary gland. These numerous studies are preceded by a general introduction written by William G. MacCallum, in which he discusses the general questions of the cancer problem and points out the lack of real progress toward the solution of the problem, many of our most modern theories being little different from those proposed long ago. However, MacCallum acknowledges that "the last ten years have contributed marvelous things," and hopes that "the next ten years may tear aside the whole veil."

This general statement of the contents of the volume serves to show what creditable amount of work has been done in the short time of the existence of the Crocker Research Fund. Its value certainly deserves the sumptuous fashion in which the articles have been gathered for publication.

LES SPOROTRICHOSES. Par M. M. DE BEURMANN, Medecin de l'hôpital St. Louis, à Paris, et GOUGEROT, professeur agrégé à la Faculté de Médicine de Paris. Avec 181 figures dans le texte et 8 blanches hors texte. Price 20 francs. Paris: Librairie Félix Alcan, 1912.

THE authors of this large volume on sporotrichoses are creators as well of almost all our knowledge of the subject. It is their labors of the last decade that have resulted in uncovering the etiology, the pathology, and the treatment of a group of affections which have previously been taken for manifestations of syphilis or of tuberculosis. With a wealth of detail the authors picture and discuss the various skin and internal lesions of sporotrichoses and especially the fairly simple clinical and laboratory methods of diagnosis of these diseases.

The book is a model monograph and the importance of the subject to anyone who may meet with intractable skin lesions or obscure cases of visceral disease is such that the accquisition of the volume should be a duty. The excellence of the work of the two French authors makes the reading of it a great pleasure as well.

THE HUNTERIAN LECTURES ON COLOR-VISION AND COLOR-BLINDNESS. Delivered before the Royal College of Surgeons of England on February 1, and 3, 1911. By Prof. F. W. EDRIDGE-GREEN, M.D. Durh., F.R.C.S. Eng., Beit Medical Research Fellow. Price $1.50 net. New York: Paul B. Hoeber, 1912.

THE Hunterian Lectures of 1911 are two in number and form a volume of 76 pages. The first lecture deals "with the theory and facts of color-vision," the second "with the detection of color-blindness from a practical point of view." Professor Edridge-Green has evolved a theory of color-perception and of color-blindness largely his own, which he discusses in detail. The evolution of the color sense is discussed. To enable one to fully comprehend the reasoning of the author one must make a careful study of the subject. The lecture on the detection of color-blindness is quite complete and is excellent. To all who are engaged in the study of or in the detection of color-blindness a perusal of Professor Edridge-Green's Hunterian Lectures will be of value.

The Soul and Sex in Education, Morals, Religion, and Adolescence. Scientific Psychology for Parents and Teachers. With a Chapter on Love, Marriage, Celibacy, and Divorce. By Josiah D. Buck, M.D. Price $1.25. Cincinnati: Stewart & Kidd Company, 1912.

This book is to some extent an attack on the methods of the Roman Catholic Church in her endeavor, according to the author, to discredit and break down the free schools of this country. Dr. Buck upholds strongly free education and declares that without it scientific knowledge cannot but suffer. The book is uninteresting.

Neurasthenia Sexualis. A Treatise on Sexual Impotence in Men and Women. For Physicians and Students of Medicine. By Bernard S. Talmey, M.D., Former Psychologist to the Mothers' and Babies' Hospital and Gynecologist to the Yorkville Hospital. With Nineteen Drawings in the Text. Price $2. New York: The Practitioners' Publishing Company, 1912.

The subject of this little work, even when discussed by medical men for medical men, requires very careful handling. When such a work is of a semi-popular nature as is the one before us extreme care is needed in compiling the facts and setting them forth so as to be of real use. Although we do not think the book is necessary, nevertheless one may gather from it some useful knowledge.

The Orientation of Buildings of Planning for Sunlight. By William Atkinson, Fellow of the Boston Society of Architects. Price $2. New York: John Wiley & Sons. London: Chapman & Hall, Ltd., 1912.

This book is written with a very excellent purpose, that of setting forth the principles which ought to govern the planning of buildings with respect to sunlight. It appears to have succeeded in its object, the chapter dealing with the orientation of hospital ward partitions being especially worthy of attention.

Nutritional Physiology. By Percy Goldthwait Stiles, Assistant Professor of Physiology in Simmons College; Instructor in Physiology and Personal Hygiene in the Massachusetts Institute of Technology, Boston. Illustrated. Price $1.25 net. Philadelphia and London: W. B. Saunders Company, 1912.

It is rather difficult to classify this small volume on nutritional physiology. It certainly makes no pretence to scientific completeness, and the popular style in which the facts are presented suggests that it is designed for high school and freshman classes in the college. It is not a book which should be given to a medical student. The contents also are not entirely devoted to what one might strictly consider nutritional physiology, as there is a chapter on the circulation of the blood with simple mechanical illustrations. A serious defect is the entire absence of references to original articles. Many textbooks are named in an appendix, but this method does not replace for the student direct reference to the work of those who have really contributed something to physiology and chemistry.

Der jetzige Stand der Krebsforschung. Von Prof. Dr. Georg Klemperer, Direktor des Instituts für Krebsforschung der Königl, Charité und des Städt, Krankenhauses Moabit, Referat, erstattet in der Generalversammlung des Deutschen Zentralkomitees für Krebsforschung am 18 Mai, 1912. Price 2 marks. Berlin: August Hirschwald, 1912.

The general interest in the study of cancer which is manifested by a large number of laboratory workers is revealed in this review of the present status of cancer investigation. Unfortunately the author has amiably included almost everything which has been published recently, without expressing his own opinion as to the weight which should be given to any individual factor. No one believes the designing quack who cures cancer by the application of herbs, but there are lesser quacks in the medical profession, and even in laboratories, who announce cancer cures with the same shamelessness as the unlicensed practitioner. So, too, there is a very great lack of appreciation of the manifold fluctuations which occur in the growth of animal tumors; how apt they are to regress spontaneously under comparatively slight influences. Many of the so-called cures by vaccination with either crushed cells or autolytic products are due to the use of animals whose tumors tend on the slightest interference with the general health of the creature to undergo spontaneous regression. Klemperer quotes right and left from just such reports, and does not state what he must know, that they lack any confirmation or any scientific probability. The little pamphlet, then, must be regarded merely as a résumé of everything which has been published recently, and it thus lacks the value which it would have had had the author expressed himself freely as to what he himself believes.

A Manual of Instruction in the Principles of Prompt Aid to the Injured. Including a Chapter on Hygiene and Disinfection. Designed for Civil and Military Use. By Alvah H. Doty, M.D., Late Health Officer of the Port of New York, Late Major and Surgeon Ninth Regiment, N. G. N. Y. Fifth Edition. Price $1.50. New York and London: D. Appleton & Company, 1912.

This work is a concise but complete account of the principles of prompt aid to the injured and the present edition, the fifth, has been brought thoroughly up to date. All relating to the subject has been included and advice is given for rendering first aid to those who meet with accidents in nearly every possible circumstance. Moreover, useful hints are given as to how to relieve certain affections which attack suddenly, as apoplexy, epilepsy, hysteria, and so on; also how to proceed in cases of poisoning. The chapters dealing with hygiene and disinfection are especially valuable, that on disinfection giving the latest views on that much debated question. The book is freely embellished with numerous cuts and diagrams illustrative of the text and provides a valuable vade-mecum for the practitioner and layman in matters concerning first aid, hygiene, and disinfection.

Further Researches Into Induced Cell Reproduction and Cancer. Vol. II. With Illustrations. The John Howard McFadden Researches. Price $1. Philadelphia: P. Blakiston's Son & Co., 1912.

This volume continues the elucidation of the theory that cell proliferation is directly brought about by chemical agents set free by cell death and is in line with the views expressed by H. C. Ross in his first book on "Induced Cell Reproduction and Cancer." This volume contains eight articles, two giving the results of attempts of experimental production of tumors by inoculation of "auxctics," or agents responsible for cell proliferation; one gives a comparison of division figures in lymphocytes, induced by "auxetics" and the classic mitotic figures; the rest discuss cancer produced in pitch workers and the behavior of certain ova and protozoa under the influence of "auxetics."

In our review of the first volume we have given a résumé of the theory promulgated by H. C. Ross and his co-workers and have noted the little credence it has met with among other students of the cancer problem. However, Ross continues to bring further data in proof of his theory of cell proliferation, and the fortunes of research are such that no man's opinion should be denied a hearing, however incredible they may seem at the time. No less an authority than Sir Ronald Ross supports his brother's views and in any case control experiments in other laboratories should be instituted to test the validity of these views and separate the chaff from the grain.

J. W. Cropper and E. H. Ross are H. C. Ross's co-workers in the present volume.

Text-book of Anatomy and Physiology for Nurses. By Elizabeth R. Bundy, M.D. Member of the Medical Staff of the Woman's Hospital of Philadelphia; Gynecologist New Jersey Training School, Vineland; Formerly Adjunct Professor of Anatomy, and Demonstrator of Anatomy in the Woman's Medical College of Pennsylvania; Formerly Superintendent of Connecticut Training School for Nurses, New Haven, etc. Second Edition Revised and Enlarged with a Glossary and 215 Illustrations, 42 of which are printed in colors. Price $1.75. Philadelphia: P. Blakiston's Son & Co., 1913.

The author of this work has done wisely in combining Anatomy and Physiology in a single volume; further, the choice of subjects for special study by nurses has been judiciously made. The book is not too large, it is well illustrated, and contains enough Anatomy and Physiology for most nurses. The index is too meager to be of much use, such important subjects as brain, blood, eye (and many others) not being entered. In the preface we are told that this new edition contains special information on the development, repair, and functions of bones; but the index gives no clue as to where this information can be found. With a new index this volume should prove acceptable to nurses, as it is vastly superior to many of the books written for this class of readers.

The Mosquito. Its Relation to Disease and Its Extermination. By Alvah H. Doty, M.D., formerly Health Officer of the Port of New York. Illustrated. New York and London: D. Appleton and Company, 1912.

This small book will serve to popularize knowledge of the mosquito and the necessity for organized effort to destroy its breeding places. The author should have emphasized how very practicable it is to exterminate mosquitos by taking advantage of the larval period since all that is required is to clean or destroy all breeding places only once in every ten days.

# Society Reports.

## PRACTITIONERS' SOCIETY OF NEW YORK.

*251st Regular Meeting, Held December 6, 1912.*

THE PRESIDENT, DR J. W. BRANNAN, IN THE CHAIR.

**Centenarians and Nonagenarians.**—Dr. W. GILMAN THOMPSON read this paper (see p. 277.)

Dr. ABBE said that what interested him most was the statement about cancer. He could recall that this was the fact in his own experience. Cancer was rare among the very old. The type of skin cancer which started as a keratosis and went on to epithelioma was explained by the theory that the cells were worn out and their self-control was lost. But it occurred in middle life. In old people it seemed to him we found repair just as active in their body cells as in young people. Bones often united very well in old people.

Dr. BACON said that he was very much impressed about the old people in the State of Maine. He went down to Cape Cod every summer and there a person was not considered old until he got to be about ninety. People there seemed to live a long time and maintained their faculties until the end.

Dr. JAMES said he did not hear the early part of Dr. Thompson's paper and he did not know what suggestion he made about opium. He was impressed with the fact that in his experience old people were sometimes benefited by opium. One old man over one hundred suffered with a condition of general misery and pain without any definite disease. He was very much benefited by opium.

Dr. BRYANT said this contribution was very interesting indeed. It was pretty generally believed that old age itself contributed more than anything else to the incidence of cancer. One might think that because people of old age had in their bodies frequently isolated tissues out of commission there might be consequently more cancer manifestations among them. Strangely he had not had very much experience with old age in the practice of surgery. He was, however, familiar with two or three persons who had attained great age, and he was struck with the statement that old people contentiously thought that they knew how to take care of themselves, but he was not impressed with the notion that old people alone were to be thus characterized. He had in mind a quite vigorous old man who was accustomed to lie down on the floor for a resting spell. He was in his 93d year and was reasoned with because it might expose him to draughts. He refused to heed advice about it and did as he wished; he contracted pneumonia and very promptly died. He had, of course, seen cases of occlusion of the vessels giving rise to gangrene, but very often this was associated with some element of infection.

Dr. THOMPSON in answer to a question by Dr. Brannan said that he had left out all those who did not die of some specific condition. There were many who simply seemed to die of no demonstrable disease.

Dr. GIBNEY presented some *x*-ray negatives in a view box—showing an extraordinary instance of fragilitasossium in a man 49 years of age. The case was seen by him two days before and the letter asking for advice contained a good history which was as follows: he had been suffering the last year from broken bones and wished to have Dr. Gibney's advice, the history of his case was briefly: In July, 1897 he fractured his left femur by a slight fall from a bicycle; in January, 1909 he slipped on the ice falling against a step and fractured his right humerus at the shoulder joint. On November 11, 1911 he slipped on a wet rock and fell, fracturing his left femur at the neck, and his left humerus. On April 10 he was up and taking a few steps with crutches. On the 14th while trying to rise from a chair on the sound leg his right femur snapped. On July 13 his doctor was lifting him from his wheel chair to the bed and while in his arms his left femur cracked slightly at the old 1897 junction. The *x*-ray showed a very thin, compact tissue while the cancellous was honeycombed, appearing in some instances like bone cysts, but the great extent of this honeycombed appearance throughout all the bones subjected to the *x*-ray, suggested a general involvement, indeed he had broken two ribs in addition to the other fractures and while repair had been very good he was afraid to bear his weight on his limbs and they must be protected by apparatus. He had never had a Wassermann test. The urine showed an abundant supply of calcium oxalate, the indican in slight excess, acid reaction, specific gravity 1018, urea 1.5 per cent., solid parts per 1,000, 41.94. Nothing else of importance. He had spent a good deal of his time out of doors. His vocation had not been a wearing one; bowels reported to be regular; appetite always good. It had been arranged that he should go into the Rockefeller Hospital for further study.

Dr. ABBE said that the subject of bone cysts had been lately illustrated by Cole and Morgan and Jones in the *Archives of Röntgen Ray*, April, 1907. They did not seem to have any reference to syphilis. There was everywhere an absence of lime salts in these *x*-rays of Dr. Gibney's patients. This would suggest a line of treatment, the giving of salts of lime.

**Carcinoma of the Choroids.**—Dr. KNAPP presented two ophthalmoscopic drawings. The first was of a case of metastatic carcinoma of the choroid. The patient, a woman of forty-two years of age, had been operated upon two years previously for carcinoma of the breast. This condition had returned in the cicatrix. The sight in the right eye became blurred about four months ago. With the ophthalmoscope, the characteristic picture of a metastatic tumor of the choroid could be seen. Hirsch, of Prague, in a recent study of these cases, states that the patient usually lives seven months after the appearance of the metastasis in the eye. In this case the patient lived seven and a half months.

**Retinal Changes in Adolescence.**—The second patient, female, aged twenty, had lost one eye from recurring hemorrhages of the vitreous. The other eye seemed normal, except, on examination with dilated pupil, round yellowish areas were found contiguous to the retinal veins in the periphery of the fundus. The case was presumably tuberculosis. Dr. Knapp asked whether in other parts of the body periphlebitic lesions were observed in a course of a tuberculous process.

Dr. ABBE suggested that if Dr. Knapp had another case of cancer of the choroid the patient should have an oophorectomy done, Beatson's operation. He had had two patients of that type in whom the nodules had disappeared after the removal of the ovaries.

Dr. KNAPP said that these cases came into his hands for eye treatment only.

## THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

*Stated Meeting, Held December 12, 1912.*

DR. WILLIAM SHANNON IN THE CHAIR.

**Protein Milk as a Means of Correcting Digestive Disturbances.**—Dr. HERBERT B. WILCOX and Dr. C. M. HILL presented this communication, in which they related their experience with protein milk. They stated that various observers had differed widely in their methods of preparing protein milk and as a result there were widely divergent percentages of fat and caloric values in the mixtures designated "protein milk." The preparation which they had used had a fat content of less than one per cent. The incentive to their study was the conclusion reached by Dr. John Howland in 1910-11 at Bellevue Hospital when protein milk was used as a routine diet for nearly all patients in the infant wards of the hospital. The conclusion which was reached at that time was that the value of protein milk depended upon its use as a corrective; that it was not to be considered as a fit means of prolonged nourishment, its period of usefulness being limited to the first seven or ten days of the dietetic treatment. In any acute digestive disturbance low fats and sugars were certainly indicated, while higher percentages of protein than they had hitherto believed advisable were now known to be well borne, and indeed actively beneficial. About 400 infants were given the protein milk as a substitute for other milk mixtures. The ages of these infants varied from prematurity to twelve months, and they were given the milk in most instances during their entire stay in the hospital, a period averaging one month. The results were most gratifying in that the children recovered from the acute evidences of their digestive abnormality, but they were usually unsuccessful in their attempts to make them gain in weight. This fact, coupled with the evidences which they had that cases of gastric indigestion, colitis, non-infectious diarrhea, and simple digestive incapacities responded with unexpected promptness led them to begin the use of protein milk as an initial corrective alone. They had deviated from the principles laid down by Finkelstein and Meyer only in the lower fat content of their mixture. They felt that the need of low fats was of first importance in treatment. They had found no need of preceding the protein milk by tea or cereal decoctions as other investigators had done. This preliminary took Finkelstein and Meyer three days and involved a great initial loss in weight. They had found

no objection to the use of protein milk in combination with other foods. They had used it with benefit in combination with plain milk mixtures, breast milk, and some solid foods. They believed that the use of the protein milk over many weeks was unnecessary and oftentimes injurious. Finkelstein and Meyer had experienced great difficulty in getting their cases changed from protein milk to other foods and advised strongly against its use with any of them. This paper showed that: 1. Protein milk was best given without a preliminary course of tea or cereal decoction. 2. That it was efficacious in all acute and chronic infections of the gastrointestinal tract. 3. That it was equally suited to fermentative and putrefactive processes. 4. That it was better given in combination with other foods than alone except for a short initial period. 5. That children on it could without danger be quickly swung over to plain milk mixtures. From May, 1911, to November, 1912, 261 children suffering from a variety of digestive disturbances were given protein milk. The large majority remained in the ward over three weeks, or long enough to justify definite conclusions as to the result. These children varied in age from prematurity to nine years. Before instituting the protein milk diet in many instances plain milk mixtures were tried for comparison. These cases were divided into three broad groups as follows: 1. Acute infections of the gastrointestinal tract, evidenced by vomiting, bad stools, and fever. 2. Apparently non-infectious indigestion due to previous nutritional abuse. 3. Simple diarrheas, namely, those in which the infants could not be given food strong enough to produce a gain in weight without accompanying gastric or intestinal overactivity. In general it might be said that protein milk was better suited to children over rather than under three months of age. Of 256 children, 72 were three months or less and of these 41 or 56 per cent. did well: 97 were from four to seven months of age and of these 76 per cent. did well; 62 were from eight to twelve months, of whom 85 per cent. did well; 25 were one year of age or over, of whom 72 per cent. did well. Among these there were many suffering from very severe digestive abnormalities. In 44 cases a trial of diet other than protein milk was first made. The improvement resulting from the use of protein milk in acute intestinal infections, as evidenced by fever, frequent bloody mucous stools, was more striking than in any other conditions. Of 44 cases of severe intestinal infections of longer duration which they had failed to correct by plain milk modifications, 70 per cent. were cured when changed to protein milk. As a means of controlling vomiting protein milk had also proved of value. Among their cases there were very few having gastric symptoms unassociated with evidences of intestinal derangement. In 74 instances, however, vomiting was the predominating symptom; of these 30 were put on plain milk modifications and 80 per cent. did well; the 20 per cent. failing to respond to this treatment were put on protein milk and all promptly recovered. Children were frequently seen who tolerated only enough food to keep their weight stationary and in whom any further addition to the dietary produced evidences of digestive overstrain. In such cases the addition of protein milk increased the food tolerance and this applied equally to fats, carbohydrates, and proteins. The indication for protein milk seemed equally clear whether the indigestion depended primarily upon fat or carbohydrate incapacity, bacterial fermentation, or putrefaction. Protein milk was not, however, a general panacea nor could it be considered the only means of controlling digestive abnormalities. It had been their experience, however, that those indigestions which did not respond to the usual methods of treatment would respond much more readily to the protein milk. Formerly every child on admission to the hospital was given castor oil as an initial purgative; now it was only the more severe cases that were given this vigorous initiation. There was reason to believe that diarrheas due to gas bacillus or bacillus disentericus or other bacterium might as logically and more easily be corrected by protein milk than by the purely bacterial starvation methods. The buttermilk which they had used was made from pasteurized milk containing 1.75 per cent. fat. To one quart of this was added one ounce of buttermilk from some reliable dairy. This was allowed to stand for twelve hours at a temperature of 70° to 80° F., being thoroughly beaten at intervals of two or three hours and then placed on ice until needed. Each day buttermilk was made from that of the preceding day, a smaller amount of stock being needed as time went on. To make the junket two quarts of pasteurized milk and two Hansen junket tablets were used. The mixture was allowed to stand twenty minutes at a temperature of 100° F.; the precipitated casein was then strained through gauze, washed in water, and forced through a fine sieve several times by means of a potato masher. The sieving was facilitated by adding buttermilk to the curd and was continued until the curd was broken into fine flakes. One grain of saccharin and one quart of water were added and the whole was thoroughly beaten to form a suspension. Protein milk thus made consisted of fat 0.8 per cent., sugar 2.4 per cent., proteid 2.8 per cent. The caloric value was 8.5 per ounce. This mixture must not be heated too quickly nor above 90° F., or tough masses of casein were likely to form. The corrective period divided itself into four parts: 1. That in which protein milk alone was given. 2. That in which protein milk plus malt sugar was given. 3. That in which much protein plus a small amount of plain milk was given. 4. That in which the protein milk was largely replaced by plain milk. The usual duration of the first stage varied from two to fourteen days. As soon as the digestion showed some improvement the malt sugar was added. They had found the dextrin maltose preferable. It was their aim to make the first period during which the protein milk alone was used as short as possible. The time necessary for the entire correction period averaged 12 days. In no case was any untoward result noticed from mixed protein milk and plain milk feedings. Protein milk was used with benefit in combination with cane, milk, and malt sugar, plain milk, and breast milk. Dr. Wilcox reviewed the history of a number of cases which illustrated the statements made in the paper.

**The Double Function of Fats and Carbohydrates in Nutrition and Their Different Nutritive Properties.**—Dr. Henry Dwight Chapin read this paper in which he showed that mere caloric value alone did not furnish a sound basis for a dietary for infants but that other factors played a rôle of considerable importance. He summarized his study by stating that fats and carbohydrates served two distinct purposes in nutrition which were equally important. They furnished energy which, when expended, liberated heat, and they also supplied water to the cells in such a manner that it diluted the cell contents and reduced their osmotic pressure so as to produce an automatic flow of nutriment to them from the more concentrated blood, as soon as it was needed. Fats were more effective producers of metabolic water than carbohydrates. Metabolic water produced from fats weighed more than the original fat and resulted from a combination of the hydrogen of the fat with the oxygen of the blood. Metabolic water derived from carbohydrates was a residual product obtained by splitting the carbohydrate and weighed about two-thirds as much as the original carbohydrate. In milk, the natural food of rapidly growing young animals which required much metabolic water to promote growth and cell nutrition, fat supplied the greater part of the metabolic water. In hen's eggs it supplied practically all of it. The amount of heat or the number of calories excreted was a measure of the food that was being burned but did not show how much was needed for growth. The energy or caloric needs of the body did not depend upon its size nor weight but upon its activity. The number of calories a food would yield was not an indication of its nutritive value. The caloric requirements of the body to maintain it intact depended upon the amount of energy expended. The number of calories the food which was to supply these requirements should yield depended upon its caloric value after deducting the number of calories needed for its digestion and assimilation. The amount of energy needed for the digestion of a food depended largely upon its physical condition. From these conclusions Dr. Chapin drew the following practical observations:

1. It was quite evident that an overemphasis had been placed upon the caloric value of foods, particularly as far as the nutrition of the infant was concerned. 2. The infants needed little food for its energy except as this was expended in the digestion and assimilation of the food. 3. Their natural food was highly specialized in composition and in digestive properties and was peculiarly suited to them. 4. Milks of various animals varied in composition and digestive properties directly with the variation of the type of the animal. 5. A proper estimation of foods, in a last analysis, depended upon digestive suitability and capacity to produce true growth and proper development.

Dr. B. Raymond Hoobler said he wished to present a chart covering the nitrogen metabolism of several children fed on protein milk. From these figures it was shown that in cases on such food the nitrogen intake was considerably higher than that usually fed to children. Though the intake was higher the absorption was excellent, 95 per cent. being absorbed, which was the same as

in a normal child. The retention of nitrogen gradually increased from day to day until supposedly the nitrogen need of the child was fully met; then the retention remained at a level, being sufficient to meet the protein need for growth. Dr. Hoobler also presented certain results bearing on the feeding of large quantities of protein as gathered from experiments made under the supervision of Dr. Holt and published in the *American Journal of the Diseases of Children*, November, 1912. The results had a distinct bearing on the various factors which caused the stools to change from a diarrheal type at the beginning of the protein milk feeding to the smooth, pasty, yellow stools which appeared after four to six days of feeding with the protein milk. These factors were: 1. There was a marked lowering of the acidity of the stools. 2. There was a marked reduction in the free fatty acids present in the stools. 3. The amount of fat in the form of soluble or insoluble soaps was much increased. 4. The amount of water lost from the body through the stools was greatly reduced. 5. The retention of mineral salts was greatly increased. All of the above factors favored the production of a change from frequent green watery stools to the smooth, pasty, yellow stools which appeared after from four to six days feeding on protein milk.

Dr. Graham Lusk said that the nutrition of the body depended upon furnishing food for maintenance, repair and growth. All of these factors appeared in the baby. The baby at the breast took food sufficient for his maintenance and about 15 per cent. in addition, which later he added to his body for growth. Instinct furnished the guide for this amount. In experiments upon adults it was remarkable that the amount of bread taken by an individual was practically constant from day to day, seldom varying more than twenty grams. Here also instinct furnished the guide for nutrition. If the baby was not nourished at the breast it was a matter of luck whether he got sufficient support for his organism. The foods administered to him were proteids, fats, and carbohydrates. Protein was made up of a great many structural units called amino-acids. These amino-acids were in number as many as the letters of the alphabet and their possible arrangement as manifold as were the words in the dictionary. The protein was broken in the intestinal tract into these several amino-acids and entered the blood in the form of amino-acids. These served to build up the varying portions of the machinery of the cells and became active portions of the machinery of cell life. There was wear and tear upon the protein constituents of the cells even in babyhood and it was therefore necessary to administer in the food sufficient protein to repair this wear and tear, and, in addition, to give enough to furnish new protein building stones for the constructive growth which was inherent in the protoplasm of the young of all species. Besides protein, however, material must be furnished to supply energy for the maintenance of the movements of life. This material was given in the form of fats or carbohydrates. There was no question but that fat might supplant carbohydrate in the nutrition of children if that were deemed necessary. Fat, on the contrary, could not supplant carbohydrate entirely because under circumstances of an exclusive fat-protein dietary acidosis appeared. It was necessary to consider the caloric requirements of the infant when a proper dietary was to be devised. This should contain during the first three months 90 calories per kilogram of body substance. In experiments which Dr. Howland had performed in his laboratory they had seen that an infant might eliminate 15 calories per hour, hour after hour, after taking a usual milk mixture. Food itself in ordinary quantities might somewhat increase metabolism. By the addition of protein to that the protein content of the milk was doubled causing an increase in the heat production of the child from 15 to 19 calories per hour. This increase was due to the specific dynamic action of protein. This was caused by the stimulation of the protoplasm through the action of certain amino-acids. It was stated that the heat value of foods was largely lost through the work expended in the digestion of the foods. However, one should remember that the breaking down of protein into amino-acids, or of fat into fatty acid and glycerin in the intestine, was not accompanied by the evolution of heat. Furthermore, if agar agar were given there was no increase in metabolism notwithstanding a great activity on the part of the intestinal tract. Benedict had shown that cathartics which strongly stimulated the intestinal tract had no effect at all upon the heat production in the organism. So the *Darmarbeit* of Zuntz as a causative factor of the increased metabolism after food ingestion must be abandoned. In Dr. Hoobler's chart two points might be observed, the addition of protein to the body not only depended upon the formula representing the composition of the milk ingested, but also upon the protein content of the organism. A large quantity of protein would be absorbed by cells whose protein supply had been depleted, whereas with the same diet a much smaller quantity of protein or perhaps none at all would be deposited by an organism whose protein content had reached a certain condition of optimum saturation. In the second place Dr. Hoobler had stated that in one of the children there was marked protein retention during a period of under nutrition and this was accompanied by a gain in weight. Dr. Hoobler's results could easily be obtained if muscle tissue were added to the body, even though tissue fat were used at the same time for the maintenance of the energy requirement of the organism. Dr. Chapin had spoken in regard to the importance of metabolic water. He, himself, had estimated that if a man of seventy kilograms net weight should produce a hundred calories of heat per hour, and this one hundred calories of heat were derived exclusively from carbohydrates, then, in the oxidation of this carbohydrate, 0.24 of a gram of water would be produced each minute. That would mean the production of three milligrams of water per kilogram of body weight or three parts of water per million parts of body weight. Since the volume of blood circulated once per minute bearing, perhaps, foods brought from the intestine, it hardly seemed possible that metabolic water amounting to three milligrams per kilogram could in any way be influential in the exchange of food between the blood and the tissues. It seemed as though the osmotic pressure of the food stuffs within the blood would be the determining factor in their passage from the blood stream to the cell.

Dr. Samuel S. Adams of Washington, D. C., said that Dr. Wilcox and Dr. Hill were to be congratulated upon the success they had obtained and particularly upon the large number of patients they had to deal with in the use of protein milk. Those who had had less experience could not speak upon the subject in such an authoritative way. The value of the report lay in the fact that the work was carried on in a class of patients with whom all were familiar in institutions where they got the very worst cases. They had tried at the Children's Hospital at Washington various treatments for gastroenteric diseases and had come to the conclusion that the severe heat and intense humidity influenced the varying mortality among infants. The Finkelstein method was followed as prescribed by the author, but the results were not such as led them to continue it long. There was great difficulty in inducing the babies to take the food. In looking over the records of children who had suffered from badly deranged digestion he had found that from eighteen to twenty-four ounces of milk mixtures were taken, but that when the babies were given protein milk, four, five, or eight ounces only were taken in twenty-four hours. The method was abandoned because of the high mortality. The cases were not selected. It seemed to him, however, that they were soon going to get better results in these cases, although they were still about as far from solving the problem of infant feeding as they were years ago. Dr. Adams asked about the mortality in institutions this year as compared with previous years and if the results from this form of treatment made any better showing. He said that in typhoid fever ten or twelve years ago the child was placed in a bath with the water at a certain temperature and excellent results were obtained; he had not ordered a bath for a patient with typhoid fever for five or six years, and the results had been better than when the baths were given. Last summer was less hot and humid and as a result the Children's Hospital showed a mortality less than for the preceding year. Dr. Adams said he had been especially impressed by what had been said regarding the therapeutic measures employed.

Dr. John Lovett Morse of Boston said he had been very much interested and entertained by Dr. Wilcox's paper, but he did not know what to say about it. He believed that Dr. Wilcox was an honest man and that he must accept his figures, but he had not seen such results in Boston with such a form of treatment. He could not see why the same form of food should affect one sort of bacteria in one way and another in another way, that was, why it should antagonize fermentation in one case and putrefaction in another. In cases of dysentery caused by the gas bacillus or allied organisms it should do good, but ought to be harmful in those caused by the dysentery bacillus which produced toxic substances from proteids. Dr. Morse said he was much interested in Dr. Chapin's paper and was indebted to him for the points he had given in regard to the use of calories. He was especially in-

debted to him for another argument in favor of fat as the infant's food.

Dr. Linnaeus Edford LaFetra said that he had been using the protein milk for three seasons, having begun it in the Babies' Hospital in 1910. His experience indicated that in severe cases of dysentery with mucus and blood in the stools, whether the result of fermentative changes or not, the protein milk was the best means of dietetic treatment that he knew of. In infants with high fever in nine out of ten cases the improvement would be very striking after the administration of protein milk for three days. He had frequently been struck by the good results obtained with this milk without regard to the type of bacterial infection. The living Bulgarian Lactic Acid Bacilli must have part of the credit for the improvement in the true dysenteric and putrefactive cases. Moreover, the protein milk increased the tolerance for other foods. This was a point that should be emphasized. At Bellevue Hospital there were instances in which infants could not take even breast milk without diarrhea and substituting protein milk for two or three feedings daily arrested the diarrhea and the breast feeding could be resumed later. The protein milk might be given with advantage in combination with other foods. He quite agreed with Dr. Wilcox in his conclusions, and especially that in the preparation of the protein milk for therapeutic purposes skimmed milk should be used. Dr. Chapin had done great service in calling attention to the fact that the calories in a food might not be at all a measure of the nutritive value of the food to the infant.

Dr. Godfrey R. Pisek said that this question of Finkelstein's method of feeding should be thoroughly threshed out, and he believed that it should be regarded only as a therapeutic measure. After using it for three or four days one could return to the breast or other feeding and get good results in a large number of cases. He believed that Dr. Wilcox was quite within the bounds in all of his conclusions. What he had said compared well with the experience of others who had used the protein in milk for a number of years.

Dr. Rowland G. Freeman said that like all receipts for infant feeding Finkelstein's milk had a limited application. Its advantages lay in the fact that it contained lactic acid bacilli in a far more palatable form than buttermilk. Its disadvantages were that it contained too much fat for many cases of diarrhea, less sugar than most children could digest, while of the protein it discarded the lactalbumin of the whey which was the most easily digested proteid, especially for infants under three months of age. Modifications of the original receipt by using skim milk or adding sugar would eliminate some of these objections. It was particularly valuable in cases with offensive stools, but often better results were obtained by feeding lactic acid bacilli in another form and then using a modification particularly adapted to the case. In regard to Dr. Chapin's paper, he believed that the estimation of the caloric values was most important, especially as a guide against underfeeding.

Dr. Charles Gilmore Kerley said that he regretted that he had not heard all of the papers. He had found protein milk a useful addition to the diet of children with diarrhea. It could be digested before skimmed milk could be tolerated and was of much use as a means of supplying the substantial nourishment when that was badly needed. Dr. Kerley felt that sugar and milk fat was accountable for not a few of the disorders of older children, a condition brought about by defective oxidation of the carbohydrates and fats. The disorders had a peculiar tendency to be cyclic in character and were represented in cyclic vomiting, recurrent bronchitis, eczema, and periodic so-called bilious attacks.

Dr. Herbert B. Wilcox, in closing the discussion, said that Dr. Adams' difficulty in getting these children to take this food might have been due to the paucity of nurses to oversee the feeding of the bottles. The child could not be left to take the bottle alone. The nipple would surely plug up and the baby become exhausted or discouraged before he had finished his meal. As to their mortality, last year it had been 34 per cent., while the year before it was 46 per cent. This decrease could not be said to be due to the protein milk alone as the death rate varied in great measure in proportion to the number of premature infants admitted and with climatic conditions. Dr. Morse's remarks were practically those he had made a year ago on the subject. They had done no bacteriological work on these patients. The report dealt with protein milk as an aid in the treatment of indigestion and was not a study of intestinal bacteria. It did not seem to him that a bacteriological examination was necessary in order to determine with what digestive abnormality they were dealing. The determination of the presence of fermentation or putrefaction should certainly be possible from the ordinary examination of the stools. Their cases were by no means all treated alike, but they all got protein milk. They got it as an adjuvant to a diet otherwise carefully modified to meet the particular needs of the case in hand.

**Election of Officers.**—*Chairman,* Dr. Henry Dwight Chapin; *Secretary,* Dr. Royal Storrs Haynes.

## SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

*Twenty-fifth Annual Meeting, Held at Old Point Comfort, Virginia, December 17, 18, and 19, 1912.*

The President, Dr. J. M. T. Finney, of Baltimore, in the Chair.

(*Concluded from page 229.*)

**The Embryogenic Relationships of Tumors of the Kidney, Suprarenal, and Testicle.**—Dr. Louis B. Wilson of Rochester, Minn., said the basis of his paper consisted of a study of the pathological specimens obtained at operation and autopsy in the Mayo clinic and a study of the human and comparative embryology of the urogenital system. The writer summarized the results of his observations as follows: *Renal Tumors:* (1) Of 92 tumors studied, there were three pelvic papillomas, 4 carcinomas, 1 squamous celled epithelioma, 1 adenoma, 1 fibroma, 7 sarcomas, 1 Wolffian tumor, 3 embryomas (Wilms' tumors), and 71 mesotheliomas. (2) The renal pelvic papilliomas and carcinomas apparently arose secondarily to chronic irritative processes of the adult pelvic epithelium. (3) The rare squamous celled epithelioma probably was a neoplastic development from the embryonic inclusion within the renal pelvis of ectoderm which had found its way into the lower end of the primitive excretory duct by way of the cloaca. (4) The embryomas of the renal cortex composed of renal and other tissues and occurring in young children were, according to Wilms, derived from inclusions of the lateral embryonic plate within th caudal portion of the nephrogenic cord in the early embryo. (5) The most numerous tumors of the renal cortex, the so-called hypernephromas or Grawitzian tumors, were apparently mesotheliomas derived from nephrogenic vesicles which had failed in the early embryo to form a tubular connection with the renal pelvis. (6) Most of the few true sarcomas of the kidney developed primarily in adult tissue of the renal capsule and involved the cortex secondarily. (7) The renal cortex was also frequently the site of inclusions from the mesonephros and rarely of inclusions from the suprarenal gland. Rarely, if ever, did either of these inclusions in the renal cortex form malignant tumors. *Adrenal Tumors:* (8) Of the 3 primary tumors of the adrenal studied, 1 was an adenoma, and the other 2 hypernephromas arising from the adrenal cortex. (9) Primary malignant tumors of the adrenal were either round-celled sarcomas or more frequently hypernephromas arising from the adrenal cortex. (10) Adrenal hypernephromas frequently induced abnormalities of sex and strength. (11) Tumors of the adrenal, in whatever stage of their development, bore no histological resemblance to most mesotheliomas (so-called renal hypernephromas). *Testicular Tumors:* (12) Of the 21 tumors of the testicle, all of the 10 which it was possible to study in histological detail were teratomas. (13) So far as could be determined, the history and histology of these 19 cases were in harmony with Ewing's hypothesis that teratomas of the testicle arose from sex cells whose normal development had been suppressed. (14) The difference in time of development of the embryonic crop of genitaloid cells and the next generation which appeared at puberty might account for variations in structure and *tempo* of the testicular teratomas.

**Prostatectomy, with Special Reference to the Sequels.**—Dr. James E. Moore of Minneapolis stated that the unsuccessful results of prostatectomy had not been as faithfully reported as the successful ones. The mortality after the upper and lower operations was practically the same in good hands, but the trend of the surgical world at the present time was toward the upper operation. Every surgeon should be proficient in both. Neither operation was a fit one for novices to experiment with, because both were serious major operations accompanied by some mortality. In the upper operation, instead of cutting through the mucous membrane in the floor of the bladder, it was better to crowd the finger into the internal meatus until the mucous membrane broke and follow through this opening with the enucleation of the prostate, as taught with the author and first published by L. L. McArthur. Con-

servatism should control these operations, but it was not conservative to postpone operation until organic changes had taken place in the bladder and kidneys. Every general practitioner should realize that when he was first called to relieve retention from enlarged prostate he was assuming a grave responsibility, because infection at this time might end fatally in spite of the surgeon's best efforts. Enlarged prostate was easy to diagnosticate, but an operation should never be recommended simply because there was enlargement. A patient should never be introduced into catheter life without first having had the advantages of prostatectomy urged upon him. Old age was not a contraindication to the operation. The results following prostatectomy were not always satisfactory even in suitable cases. Patients frequently returned to the family physician after having been operated upon in very little better condition than before the operation, and sometimes worse. Impotence followed the operation in a certain percentage of cases, and nntil we knew just what caused the impotence we would be unable to prevent it. It was probably due to disturbance to the nerve supply. Gangrene of the bladder was an occasional sequel, to be prevented by handling the tissues as gently as possible. Careful search for stone should be made at every operation, because many times they had been overlooked. They undoubtedly formed after the operation in some cases. This should be prevented by emptying the bladder of blood clots and all detritus. When the bladder was in a reasonably good condition the cystoscope might be used to advantage, but with a badly infected bladder it did more harm than good, and catheterization of the ureters was unwarranted. With improvement in our technique urinary fistulæ were much less frequent than formerly, but were still an occasional sequel in cases that required unusually prolonged drainage. In cases of atony of the bladder the patient should be told that he would probably have to continue the use of the catheter after the operation, but that catheterization would be much easier and more comfortable. Incontinence or dribbling was an occasional sequel after both operations, due to injury to the sphincters or their nerve supply. To prevent this sequel the sphincters should be entered as little as possible, and in the upper operation more careful closing of the wound should be performed. The tendency in the upper operation was toward the more complete closing of the wound. While present day prostatectomy was one of the most beneficial operations at our command, the number of failures and sequels was too numerous. Might not less radical measures be better, such as removing the third lobe and dilating the prostatic urethra through a suprapubic opening, which was accompanied by neither complications nor sequels?

**Fat Hernia.**—Dr. Joseph Ransohoff of Cincinnati reported seven cases. According to his conception, certain characteristics accompanied the primary fat hernia: (1) A true fat hernia was a protrusion of a preperitoneal fat mass or lipoma through one of the ordinary hernial apertures. It followed the course pursued by an ordinary hernia. (2) When a peritoneal process was found within such a hernia, it was always difficult to find because of its small lumen. Such a process when present, in a minority of his cases, was secondary to the fat hernia and probably resulted from traction. The ordinary contents of a hernia were not found and could hardly enter into the narrow serous tube within the fat mass. (3) The onset of a fat hernia might be sudden, like that of the ordinary type of hernia with preformed sac. In three of the cases recorded the history of sudden onset was very clear and the proportion of cases too large to be charged to inaccuracy of observation on the part of the patient. (4) The diagnosis of fat hernia was far from easy. Although not reducible, they were capable of a seeming reduction in a fair proportion of cases. (5) An impulse on coughing could usually be obtained, since the hernia could receive the brunt of the increase of intraabdominal pressure like an ordinary reducible hernia. (6) In very rare instances symptoms of strangulation might result from torsion of the fat hernia. (7) The treatment of fat hernia differed in no way from that of the ordinary type. It was probable that these cases would only be recognized as fat hernias during the operation, therefore, measures for radical cure would be instituted, such as those in vogue for the ordinary forms of hernia.

**Experimental Devascularization of the Intestines with and without Mechanical Obstruction.**—Dr. J. Shelton Horsley and Dr. C. C. Coleman of Richmond, Va., contributed a joint paper in which they reported twelve experiments, all on dogs, done under full anesthesia in which segments of intestine from the lower ileum, varying from two to five inches, were devascularized by cutting the attachments of the mesentery close to the bowel. In all except one the omentum was wrapped around the devascularized segment. In five instances the segment was obstructed by tapes at each end. Two of these dogs died from gangrene and perforation of the loop. One died after three days without perforation; one lived thirteen days, and the other lived fourteen days. In seven dogs a loop of intestine was devascularized without being obstructed and the omentum wrapped around the segment. None of these dogs died as a result of the operation. The authors concluded that either no toxic substance was formed in the devascularized loop or segment of intestine which was unobstructed, or else this substance, if formed and excreted, was not absorbed by the normal mucosa. They emphasized the fact that in dogs at least a loop of bowel when separated from its mesentery and unobstructed might be nourished by wrapping the omentum around it.

**Acute Hematogenous Infection of the Kidney.**—Dr. J. M. Mason of Birmingham, Ala., read a paper on this subject in which he reported three cases and summarized as follows: "1. Acute hematogenous infection or septic infarct of the kidneys is of comparatively frequent occurrence, and is often overlooked. 2. Serious injury to or disease of one kidney acts as a predisposing cause. 3. While nephrectomy is demanded in the fulminating type, early diagnosis and operation will permit of decapsulation with incision and drainage of infarcts in certain of the milder cases, thereby saving some kidneys which would require removal if treated later. 4. The relation of movable kidney to the development of septic infarct offers an indication for nephropexy worthy of consideration. 5. When exploration in acute supposedly abdominal conditions fail to reveal lesions sufficient to account for the symptoms present, the possibility of septic renal infarct should be borne in mind and the condition of the kidney ascertained before completing the operation."

**Head Injuries.**—Dr. Ap. Morgan Vance of Louisville reported eight cases.

Case I. Patient, twelve years before operation, was struck on the head with a shovel, followed by the development of epilepsy. Operation twelve years later at the site of injury consisting of the removal of a good sized button, resulting in complete recovery. There were no further epileptic seizures. The patient died of pneumonia ten years later.

Case II. Patient, forty-five years old, became paralyzed two days before operation ,and gradually lapsed into complete coma and developed paralysis, beginning on the left side and extending to the whole body, including the face. Sensation on the left side was entirely absent, and greatly diminished on the right. Bowels and bladder paralyzed; eye reflexes absent. Operation: Upon shaving the scalp the head showed a curious condition. The whole scalp was edematous and the right half presented the appearance of angioma, the veins were so greatly dilated. A piece of bone the size of a ten cent piece was removed and the opening then enlarged to the size of half a dollar. The dura was incised, the brain explored with suction needle, and one-half ounce of fluid obtained. Wound was closed without drainage. Complete recovery. This condition resembled very much what is designated by two or three authors as "wet brain."

Case III. Boy, aged ten, head injury in street car accident. Scalp torn from both sides of the skull. Loss of the parietal bone. Scalp cleansed, parts adjusted and separate dressings applied. Twelve days later, with the patient in good condition, another doctor was called to soak the dressing off, which the speaker declined to do. The uncovered meninges became infected, and the boy died three days later.

Case IV. Injury of the skull in the right perietal region, patient being struck on the head by a baseball. Decompression operation nine weeks later, with removal of a good-sized button. Complete recovery, with no recollection by the patient of the accident.

Case V. Boy, aged ten, sustained extensive compound, comminuted fracture of the skull. The mastoid region and the area back of and above the ear were crushed. Operation consisted of removal of several pieces of bone, the scalp being sutured without drainage. Complete recovery.

Case VI. Epilepsy, with loss of speech and power of locomotion following an injury to the head. Examination revealed depression over the left brow and temporal region. Operation consisted of removal of a large piece of bone without subsequent drainage, followed by complete recovery.

Case VII. Pistol wound at the junction of the frontal with the parietal bone, large enough to admit one's thumb. Operation consisted of removal of fracture with some brain matter as well as fragments of bullet, followed by complete recovery.

Case VIII. Pistol wound through the roof of the mouth, a little anterior to the junction of the soft with the hard palates, the bullet going entirely through the brain. No operative measures were carried out at this time. Mouth sprayed with antiseptic fluids and liquid nourishment given. At the end of six weeks the bullet was removed, together with several pieces of the skull. This was followed by complete recovery.

**The Surgery of the Single and Horseshoe Kidney.**—Dr. Charles H. Mayo of Rochester, Minn., stated that developmental abnormalities of the genitourinary system were the most frequent. Of this group irregularities of the circulation of the kidney were the most common. Their own autopsy records had shown in a single year as high as 4 per cent. of cases presenting gross anomalies of the kidney and ureter of surgical importance. That it was necessary for the surgeon to thoroughly understand these anomalies was obvious, from several points of view. A knowledge of the early development of the genito-urinary system made intelligible the resultant anomalies and various pathological conditions. We saw the possible development of congenital, cystic kidney resulting from a failure of certain portions of the secreting renal tissues to become united with the collecting portion. Wilson had called attention to the probable development of the so-called hypernephromata as neoplastic growths from similarly unattached secreting portions of the kidney. Among 36 cases of gross renal and ureteral anomalies observed in their clinic during five years, 7 were found incidentally to other abdominal operations, 12 were of the horseshoe type, and 6 of the single or asymmetrical type. Of 649 operations on the kidney and ureters during this period of five years, there was an average of one serious anomaly associated with disease in every 26 cases. In the horseshoe form 90 per cent. were fused at the lower pole. At the point of union there might be only connective tissue (in 15 per cent. of the cases). Usually the fusion consisted of renal tissue and varied from a small area to the full width and thickness of the kidney. Ninety per cent. of cases were fused in front of the great vessels. The most common disease affecting horseshoe kidney was hydronephrosis which might later develop into pyonephrosis. This hydronephrosis occurred in moderately young individuals, while pyonephrosis and lithiasis were usually seen in middle age or later. Tuberculosis was rarely seen. More horseshoe kidneys were found in women than in men, and more single kidneys in men than in women. When the kidneys were fused by heavy renal tissue, symptoms might undoubtedly be present. Rovsing recently published cases in which the diagnosis was confirmed at operation. Despite the diagnostic data which had been given, as a rule the condition would not be recognized before operation. Braasch indicated, in addition to the cystoscope and radiograph, the great assistance of pyelography with colloidal silver injections. The lesson to be learned, when we did not have absolute data as to the condition of both kidneys, was to always explore the other kidney, usually through a separate incision, before the removal of a tumor of the kidney or the removal of a diseased kidney. In abdominal surgery, where the type of the presenting tumor was questionable, the kidney should be palpated before removal of the tumor. In some instances transperitoneal incision was indicated. The lateral incision described by W. J. Mayo would suffice in most cases. At operation the possibility of horseshoe kidney must be kept in mind, especially whenever difficulty was experienced in delivering the lower pole. This occurred in the writer's last case, where pyonephrosis of half of the horseshoe kidney was present. The renal tissue, nearly the size of the normal kidney, passed in front of the large vessels. After examination of the blood supply, the fused portion was divided and sutured with catgut. In a case of horseshoe kidney, which was not otherwise pathological, Rovsing relieved the pain and general symptoms by division of the isthmus.

**A Cheek Defect and Its Repair by Plastic Operation.**—Dr. John Staige Davis of Baltimore reported the following case: Male, aged 16. Defect 6.3 centimeters in diameter, involving the whole thickness of the right cheek. Probably caused by cancrum oris, which occurred as a typhoid complication two years previously. The surrounding soft parts were infiltrated with scar tissue. The tongue was adherent to the lower border of the defect. There was inability to open the jaws. To close this defect a flap was necessary, which should fulfill several conditions. It should have enough thickness to fill the defect without causing a depressed scar after healing was complete. It should be formed of tissue which would conform in appearance to the surrounding skin externally, and take the place of the mucous membrane of the mouth. A rectangular flap 7.5 x 16 centimeters, of whole thickness of skin and subcutaneous fat, was raised from the right arm. The pedicle was in the mid-deltoid region. The flap was folded on itself and the distal end sutured to the pedicle and underlying muscle, thus bringing raw surface to raw surface and forming a flap with fat within, and the whole thickness of the skin on front and back. This was half flat on a wire frame. Two weeks later the tongue was freed, the arm was raised and the flap was sutured into the upper two-thirds of the defect. The arm was held in position by a plaster cast. The pedicle was amputated after eleven days, and eleven days later the remainder of the opening was completely closed. Several attempts were made to relieve the fibrous ankylosis of the jaws, but without success. By this method of treatment the defect was filled by a pad of tissue with the whole thickness of the skin on both sides. The circulation of the flap was assured before transplantation was begun. Most of the shrinkage had taken place before it was transplanted. There was no unsightly scarring of the cheek or neck. The area from which the flap was secured was healed by Thiersch grafts by the time the flap was ready for transplantation. On the whole, the result was very satisfactory.

**The Diagnosis and Treatment of Renal and Ureteral Calculi.**—Dr. John B. Deaver of Philadelphia reported sixty cases of renal and ureteral calculi. Attacks of typhoid preceded the onset of symptoms of stone. A catarrhal condition of the pelvic and ureteral mucosa was the chief predisposing factor in the formation of kidney and ureteral stones. The initial symptoms were attacks of renal colic, trauma, falls, blows, or kicks over the kidney area. Repeated attacks of colic were more frequently due to stones in the ureter. Location, type, frequency of attacks and points of reference of same indicated the site of the stone. Physical examination in cases of aseptic and uncomplicated renal and ureteral calculi gave no assistance in diagnosis in one-half or more of the cases, but was of more assistance in renal than in ureteral cases because of the presence of a palpable mass in a percentage of cases. The diagnosis was much facilitated in difficult cases by the use of pyelographic methods. Tenderness and muscular rigidity were the most important physical signs. Microscopic hematuria immediately following a severe attack of colic was suggestive of stone. The skiagraph was the most valuable means at our disposal in the diagnosis of urinary calculi. In five of his cases the *x*-ray failed to find the stone, which in three instances was found at operation in the ureter once, and in the kidney twice. The use of waxed tipped catheters was said to be in these rare cases the court of last appeal in diagnostic procedure, but the speaker relied entirely on the clinical history. The most frequent causes of ureteral obstruction were either physiological or anatomical. Before attempting any operation it was necessary to satisfy one's self as to the functional activities of the renal tissue, to be assured that the reserve force of the healthy, or, at least, diseased kidney was sufficient to sustain the renal function in the event of the necessity of nephrectomy, which could not always be foretold. Stones situated in the lower terminal (2.5 cm. of the ureter) were removed transvesically. In renal calculus the kidney was exposed and, if possible, delivered through an oblique loin incision; the stone was palpated and an incision made over it and the stone removed with forceps. In nine instances palpation failed to demonstrate the presence of stone. In five of these it was correctly located with the needle. Needling was a practical, harmless, and valuable procedure in cases in which palpation failed. The total mortality in the operated cases of this series was 6.5 per cent.

The following papers were also read: "A Fetal Type of Cecum in the Adult," by Dr. W. C. Borden, Washington, D. C.; "President's Address: Surgical Judgment," by Dr. J. M. T. Finney, Baltimore, Md.; "Identity of the Cause of So-Called Post-Operative Hyperthyroidism and Post-Operative Wound Fever, and the Method of Controlling Both, with Lantern Illustrations," by Dr. Geo. W. Crile, Cleveland, Ohio; "Gastric and Duodenal Ulcers, with Special Reference to the Method of Operative Procedure Employed," by Dr. Frank Martin, Baltimore, Md.; "The Operative Complications of Prostatectomy," by Dr. Francis Hagner, Washington, D. C.; "The Pseudo-Peritoneal Caul of the Colon," by Dr. John W. Long, Greensboro, N. C.

**Pseudoperitoneal Cauls of the Colon.**—Dr. John Wesley Long of Greensboro, N. C., considered the nomenclature of the subject, analyzing the terms, adhesions, membranous pericolitis, veils, pseudomembranes, etc., which were ordinarily applied to the condition described. He showed that we often used very inexact terms in speaking of the membranous formations found about the colon. He proposed the term "pseudoperitoneal caul" as being descriptive and withal correct. Caul means a thin serous membrane, and was especially applied to peritoneal mem-

branes as the layers forming the great omentum. The membranes in question were evidently of peritoneal origin and by the testimony of the majority of writers they were a new formation, therefore pseudo; hence the term, "pseudoperitoneal caul of the colon." There were four chronic conditions found in the right iliac fossa, namely, chronic appendicitis, Lane's kink, Jackson's membrane, and cecum mobile, all of which had much in common as to etiology, pathology, and symptom complex, and were difficult to differentiate clinically. Of this group the writer laid stress on the pseudoperitoneal cauls of the colon, and believed them to be largely of infectious origin, though he did not deny the influence of developmental errors, splanchnoptosis, and intestinal stasis. Dr. Long showed a drawing, with lantern slide picture, of a typical case of pseudoperitoneal caul of the colon (Jackson's membrane) which was embodied in a paper that he read before the American Association of Obstetricians and Gynecologists in 1896, and published in the *International Journal of Surgery* in December of the same year.

**Officers.**—The following officers were elected: *President,* Dr. John Young Brown, St. Louis, Mo.; *Vice-Presidents,* Dr. Ap Morgan Vance, Louisville, Ky., and Dr. Lomax Gwathmey, Norfolk, Va.; *Treasurer,* Dr. Le Grande Guerry, Columbia, S. C.; *Secretary,* Dr. William D. Haggard, Nashville, Tenn.

Atlanta, Georgia, was selected as the place for holding the next annual meeting, in December, 1913.

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DIE KRANKHEITEN DES VERDAUUNGSKANALS. By Dr. PAUL CONHEIM. 275 pages; paper; price, 8.60 M. Carl Marhold, Publisher, Berlin.

KRIMINAL-ANTHROPOLOGIE. By Dr. L. M. KOTSCHER. 1,267 pages; paper. S. Karger, Publisher, Berlin.

LE DIAGNOSTIC ET LE TRAITEMENT DES CANCERS INOPERABLES. By Dr. JOSEPH THOMAS. 158 pages; paper. A. Maloine, Publisher, Paris.

MEDIZINISCH-CHEMISCHES LABORATORIUMS-HILFBUCH. By Dr. LUDWIG PINCUSSOHN. 443 pages; illustrated; cloth; price, 13.50 M. F. C. W. Vogel, Publisher, Leipzig.

THE MEDICAL RECORD VISITING LIST OR PHYSICIANS' DIARY FOR 1913. William Wood & Company, Publishers, New York. Price, $1.50 to $4.

THE PHYSICIAN'S VISITING LIST FOR 1913. Price, $1.25 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

GOULD AND PYLE'S CYCLOPEDIA OF PRACTICAL MEDICINE AND SURGERY. By R. J. E. SCOTT, M.A., B.C.L., M.D. Second Edition. 653 illustrations; cloth; price, $12 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

CLINIQUE ET THÉRAPEUTIQUE OBSTETRICALES DU PRACTICIEN. By PAUL RUDAUX, A. GROSSE, and V. LE LORIER. 890 pages; cloth; price, 8 fr. Vigot Frères, Publishers, Paris.

DISEASES OF CHILDREN. By BENJAMIN KNOX RACHFORD. 783 pages; illustrated; cloth. D. Appleton & Company, Publishers, New York and London.

A TREATISE ON PELLAGRA. By EDW. JENNER WOOD, S.B., M.D. 377 pages; illustrated; cloth. D. Appleton & Company, Publishers, New York and London.

ANESTHETICS AND THEIR ADMINISTRATION. By SIR FREDERIC W. HEWITT, M.V.O., M.A., M.D. Fourth Edition. 676 pages; illustrated; cloth; price, $5 net. The Macmillan Company, Publishers, New York.

SLEEP AND THE SLEEPLESS. By JOSEPH COLLINS, M.D. 129 pages; cloth; price, $1.00 net. Sturgis & Walton, Publishers, New York.

NEW ASPECTS OF DIABETES. By Prof. Dr. CARL VON NOORDEN. 160 pages; cloth; price, $1.50 net. E. B. Treat & Company, Publishers, New York.

A STUDENT'S MANUAL OF SURGICAL DIAGNOSIS. By GEORGE EMERSON BREWER, M.D. 40 pages; paper. D. Appleton & Company, Publishers, New York.

DER HAFTAPPARAT DER WEIBLICHEN GENITALIEN. By Dr. EDUARD MARTIN. 60 pages; illustrated and 24 plates; cloth; price, 25 M. S. Karger, Publisher, Berlin.

THE HISTORY OF THE PRISON PSYCHOSES. By Drs. PAUL NITSCHE and KARL WILMANNS. 84 pages; paper; price, $1.25. The Journal of Nervous and Mental Disease Publishing Company, Publishers, New York.

INVESTIGATIONS ON EPIDEMIC INFANTILE PARALYSIS. Report from the State Medical Institute of Sweden to the XV International Congress on Hygiene and Demography, Washington, 1912. 271 pages and 7 plates; paper. Published by the State Medical Institute, Sweden.

LE POST PARTUM NORMAL. By Prof. CONSTANTIN DANIEL. 137 pages; paper. A. Maloine, Publisher, Paris.

ANATOMIE DES NERVENSYSTEMS. By Prof. L. JACOBSOHN, Dr. W. FRANKFURTHER, and Dr. A. HIRSCHFELD. 94 pages; paper. S. Karger, Publisher, Berlin.

PHYSIOLOGIE DES NERVENSYSTEMS. By Dr. HUGO WIENER, GEORG PERITZ, OTTO KALISCHER, G. F. NICOLAI, MEYER LIERHEIM, WALTER MISCH, and AUGUSTE LOTZ. 281 pages; paper. S. Karger, Publisher, Berlin.

ETUDES D'ENDOCRINOLOGIE. By Dr. Naame. 74 pages; paper. A. Maloine, Publisher, Paris.

PROCEEDINGS OF THE ROYAL SOCIETY OF MEDICINE. Vol. VI, No. 1—November, 1912. Illustrated; paper; price, 7s. 6d. Longmans, Green & Company, Publishers, New York.

E. MERCK'S ANNUAL REPORT OF RECENT ADVANCES IN PHARMACEUTICAL CHEMISTRY AND THERAPEUTICS. Vol. XXV. 508 pages; paper. E. Merck, Publisher, Darmstadt.

MOTOR CAR ANATOMY. By Franklin Pierce. 80 pages; illustrated; cloth. The Buckeye Manufacturing Company, Publishers, Anderson, Ind.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. By Dr. L. Katz, H. Preysing and F. Blumenfeld. Vol. III, No. 5. 528 pages; illustrated; paper; price, 7 M. Curt Kabitzsch, Publisher, Wurzburg.

OUTLINES OF PSYCHIATRY. By William A. White, M.D. Fourth Edition. 318 pages; illustrated; paper; price, $3. Journal of Nervous and Mental Disease Publishing Company, Publishers, New York.

REPORT OF THE PELLAGRA COMMISSION OF THE STATE OF ILLINOIS. 250 pages; illustrated; paper.

THE MODERN MATERIA MEDICA. Third Edition, 282 pages; cloth. The Druggists' Circular, Publishers, New York.

BULLETIN FROM THE ROYAL VICTORIA HOSPITAL, No. 2. Edited by O. C. Gruner, M.D. 165 pages; illustrated, paper.

QUARTERLY REPORT OF BUREAU OF HEALTH FOR THE PHILIPPINE ISLANDS—Second Quarter, 1912. By Victor G. Heiser, M.D. 53 pages; paper.

TEXT-BOOK OF GENERAL AND SPECIAL PATHOLOGY. By Henry T. Brooks, M.D. 1127 pages; illustrated; cloth; price, $5.00 net. F. A. Davis Company, Publishers, Philadelphia.

GENITOURINARY DISEASES AND SYPHILIS. By Henry H. Morton, M.D. Third Edition. 605 pages; illustrated; cloth; price, $6.00 net. F. A. Davis Company, Publishers, Philadelphia.

FLATULENCE AND SHOCK. By F. G. Crookshank, M.D., M.R.C.P. 47 pages; cloth; price 2s. net. H. K. Lewis, Publisher, London.

INTERNATIONAL CLINICS. Edited by Henry W. Cattell, A.M., M.D. Vol. IV. 22nd Series. 298 pages; illustrated; cloth; price, $2.00. J. B. Lippincott Co., Publishers, Philadelphia.

DISEASES OF WOMEN. By Thomas George Stevens, M.D., B.S., F.R.C.S., M.R.C.P. 431 pages; illustrated; price $5.50. Oxford University Press, Publishers, New York.

DISEASES OF THE EYES. By C. Devereux Marshall, F.R.C.S. 303 pages; illustrated; cloth; price, $3.75. Oxford University Press, Publishers, New York.

TREATMENT AFTER OPERATION. By William Turner, M.S., F.R.C.S. and E. Rock Carling, B.S., F.R.C.S. 247 pages; illustrated; cloth; price, $3.75. Oxford University Press, Publishers, New York.

TEXT-BOOK OF OPHTHALMOLOGY. By Dr. Paul Roemer, translated by Dr. Matthias Lanckton Foster; 571 pages; illustrated; vol. 2; cloth; price, $2.50 net. Rebman Company, Publishers, New York City.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Edited by Archibald MacLaren, M.D. Illustrated; vol. 30; cloth; 758 pages. Published by the Society.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. Vol. 12, Part 3, 688 pages; paper. Published by the Society.

LA VIRULENCE DES PNEUMOCOQUES. By L. Cotoni. 96 pages; paper. G. Steinheil, Publishers, Paris.

ELEMENTARY BIOLOGY—ANIMAL AND HUMAN. By James Edward Peabody, A.M. and Arthur Ellsworth Hunt, Ph.B. 212 pages; illustrated; cloth; price, $1.00 net. The Macmillan Company, Publishers, New York.

BEITRAGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITATSFORSCHUNG. Vol. 1, No. 1. By Prof. Dr. L. Brauer. 212 pages; illustrated; paper; price, 20 M. Curt Kabitzsch, Publisher, Wurzburg.

## Therapeutic Hints.

**Thyroid Treatment of Epilepsy.**—E. Gelma records the happy results following the use of thyroid extract in cases of epilepsy associated with goiter, myxedema, or some other perversion of the activity of the thyroid gland. The following are enumerated as signs of slight degrees of hypothyroidism: Permanent or transitory edema, nasal obstruction, frequent muffling of the voice, falling out of the hair of the eyebrows, canities, alopecia, anomalies of heat regulation, headaches, somnolence, precocious senility, and various nervous disorders. The author has obtained the best results in the treatment of these conditions with the dry extract of the thyroid gland, administered in doses of 50 centigrams. This drug is particularly of value in the treatment of infantile convulsions.—*Revue de Médecine,* January 10, 1913.

**Lumbar Puncture in the Treatment of Headaches.**—H. Roger and J. Baumel allude to the value of lumbar puncture in the relief of the intense headaches associated with the various infectious diseases. In these cases, whether the condition be called one of meningism or of meningeal reaction, or of serous meningitis, or of chemical meningitis, there is distinct evidence of a mild degree of inflammation of the meninges. This evidence consists in the increase in the content of albumin in the cerebrospinal fluid. A later stage of the inflammatory process is accompanied by the exudation of leucocytes, and finally by the actual passage of bacteria into the cerebrospinal fluid. At the same time there is an increased tension in the cerebrospinal fluid. If this is marked one may safely remove by lumbar puncture as much as 20 to 30 c.c. of the fluid. In the ordinary run of cases the removal of 10 c.c. of fluid is sufficient. Relief follows a few minutes after the operation and in some cases the headache disappears entirely. In certain instances, as in some cases of typhoid fever, several punctures may be necessary. Syphilitic headaches, particularly those belonging to the secondary period of this disease, are markedly relieved by this procedure.—*Revue de Médecine,* January 10, 1913.

**The Treatment of Pertussis.**—M. Landolfi notes that the large number of remedies that have been proposed in the management of this disease indicate that there is no ideal method of treatment. The following has been recommended by Concetti:

℞ Codeine sulphate, 0.02 gram.
Antipyrine, 1 gram.
Resorcin, 2 grams.
Distilled water, 70 c.c.
Tincture of opium, 3 drops.
Tincture of belladonna, 8 drops.
Simple syrup, 10 grams.
Syrup of lemon, 20 grams.

Of this mixture there is given every one to two hours to an infant less than one year old, a teaspoonful; to a child from one to three years of age, a dessertspoonful; and to a child more than three years old, a tablespoonful.

Fede prescribes according to the age of the patient from two to five drops of the tincture of belladonna, or one gram of sodium bromide, or 0.5 milligram of morphine hydrochloride, repeating the dose according to the effect. In some cases he has obtained good results with the use of a 3 per cent. solution of resorcin sprayed into the throat by means of an atomizer four times a day, or by applying this solution to the throat by means of a camel's hair brush. In a similar manner he has employed a solution of corrosive sublimate (1/1000) twice a day. The amygdalate of antipyrin (tussol) has been prescribed as follows:

℞ Amygdalate of antipyrin (tussol), 1 to 3 grams.
Water, 100 grams.
Simple syrup, 20 grams.
S. One teaspoonful every 2 hours.

A remedy which has demonstrated its efficacy but which must be employed with considerable caution is bromoform, which may be given in milk in the dose of three drops per diem for every year of age of the infant. (L. Ferrannini.) Marfan advises the following:

℞ Bromoform, 38 drops.
Oil of sweet almonds,
Gum arabic, of each, 15 grams.
Cherry laurel water, 4 c.c.
Distilled water, sufficient to make 120 c.c.
S. To be well shaken. Dose, one teaspoonful.

Cavazzani has obtained good results with iodine:

℞ Iodine, 1 gram.
Potassium iodide, 15 grams.
Distilled water, 15 grams.
S. Four to six drops per diem to an infant one year old; six to nine drops to a child two to five years old; and ten to fifteen drops to a child older than five years. The dose may be administered in sweetened milk, or in coffee.
—*La Riforma Medica,* January 18, 1913.

**Treatment of the Painful Dysphagia of Laryngeal Tuberculosis.**—Castex recommends the following solutions that may be applied to the tuberculous larynx:

℞ Crystallized menthol, 2 grams.
Tincture of eucalyptus, 20 grams.
Alcohol, 140 grams.
Distilled water, 340 grams.
℞ Anesthesin, 3 grams.
Absolute alcohol, 45 grams.
Distilled water, 55 grams.

Moure's formula is as follows:

℞ Morphine hydrochloride, 0.25 to 0.60 gram.
Cocaine hydrochloride, 0.50 to 1 gram.
Adrenalin (1 to 1000 solution), 2 to 5 grams.
Glycerin,
Cherry laurel water, of each, 50 grams.
Water, 400 grams.
—*Gazette des Hôpitaux.*

**Treatment of the Chronic Purpuras of Infancy.**—Deléarde and Hallez recommend the subcutaneous injection of adrenalin, the administration of acidulated drinks, and above all, of calcium chloride. Marfan advises the administration of a tablespoonful of the following solution twice daily:

℞ Calcium chloride, 8 grams.
Distilled water, 1000 c.c.

P. E. Weill recommends the use of subcutaneous or intravenous injections of fresh horse serum or even of antidiphtheric serum. Nobécourt and Tixier have recently called attention to the use of subcutaneous injections of Witte's peptone. The solution is made up as follows:

℞ Witte's peptone, 5 grams.
Sodium chloride, 0.5 gram.
Distilled water, 100 c.c.

This solution is turbid when cold, but it is clarified by boiling. It is filtered when hot, and is sterilized at a temperature of 120°C. The liquid is injected in doses of 6 or 7 cubic centimeters every two or three days.—*Gazette des Hôpitaux.*

## Original Articles.

### THE TREATMENT OF DISEASES OF VEGETABLE PARASITIC ORIGIN BY DEEP INJECTIONS OF MERCURY.

BY BARTON LISLE WRIGHT, M.D.,
SURGEON, UNITED STATES NAVY.

SINCE 1908 I have reported several hundred cases of tuberculosis treated by deep muscular injections of mercury, but it was not until March 18, 1911, that I published[1] my belief that mercury is the chemical affinity of the tubercle bacillus. From this it was but a natural and logical step to my theory: For every vegetable organism mercury is the chemical affinity, expressed by chemical formula as follows: *(Vegetable antigen + Hg) + Antibody + Complement = Complement fixation (cure).*

This theory was published[2] December 2, 1911. It was supported by the report of the following cases: One case of acute miliary tuberculosis of pulmonary type, two cases of pulmonary tuberculosis, one case of bronchopneumonia, three cases of typhoid fever, and the following cases of staphylococcic origin: five cases of epidemic catarrh, ten cases of follicular tonsillitis, one case of cystitis, one of cellulitis, one of chronic otitis media, and four cases of furunculosis.

In a third paper,[3] which appeared June 1, 1912, in further support of my theory, I reported the following: four cases of croupous pneumonia, two cases of bronchopneumonia, and six cases of gonorrheal arthritis.

Since then I have treated the following cases with the results noted below:

*Typhoid Fever.*—Case XXXIX.—Admitted March 23, 1912, at 1 P. M.; stated that he had not felt well for some days. Complaint: Head and backache, profound malaise. Temperature 103.6°, pulse 100, respirations 21, rather marked mental hebetude. $MgSO_4$ gm. 30 (℥ i). March 24 about the same time, had five or six nasal hemorrhages during the afternoon. March 25—Symptoms in the morning apparently worse, abdomen slightly tender, pains and tenderness over spleen. Urine showed motile bacilli; 9:50 A.M., injection mercuric succinimide, gm. 0/110 (gr. 17/10); immediate improvement (see chart No. 1), several nasal hemorrhages during the afternoon; temperature began to fall by lysis. March 26—About same, 1 P.M., injection mercuric succinimide, gm. 0.084 (gr. 13/10). From this time on the patient made an uneventful recovery and was discharged to duty April 6.

CASE XL.—Admitted 7 P.M., March 25, 1912,

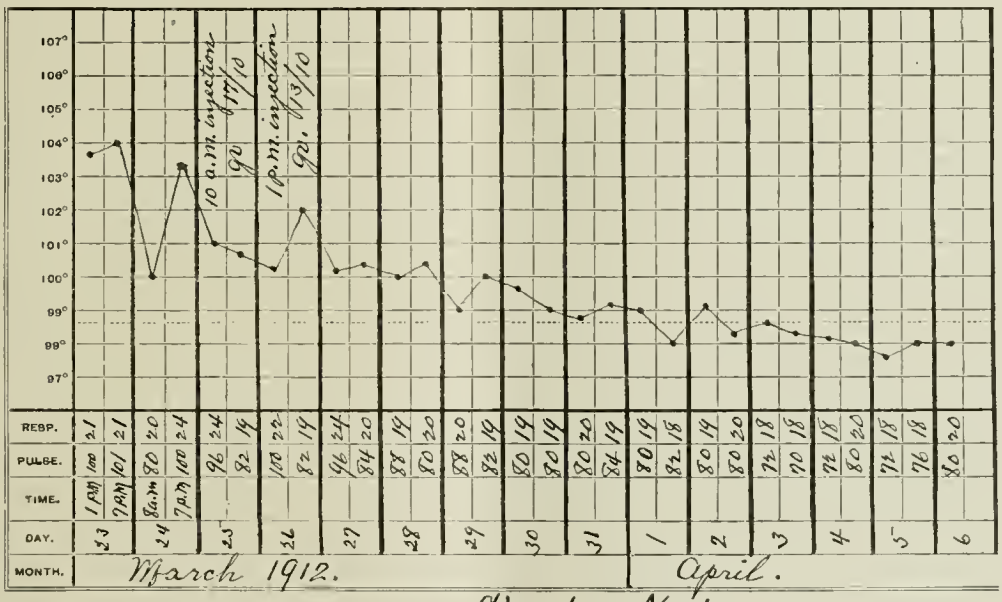

Chart No. 1.

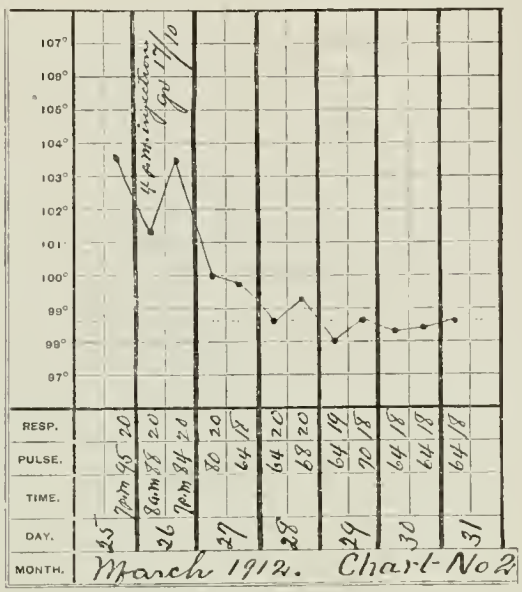
stated that he had not felt well for a week or ten days. Complaint: headache, profound malaise and constipation. Temperature 103.6°, pulse 95, respirations 20. OI. ricini 30 c.c. (f℥i). Large movement of bowels 8 P. M. March 26—No change. Urine shows motile bacilli in large numbers. 10 A.M., temperature 104°, pulse 88, respirations 20. 4 P.M., injection mercuric succinimide gm. 0.110 (gr. 17/10), immediate improvement. 10 P.M., temperature 102, patient felt much better. March 27—Marked improvement. 8 A.M., temperature 100°, pulse 80, respirations 20. Termination by crisis. See Chart No. 2. From this time on convalescence uneventful, discharged to duty March 31, 1912.

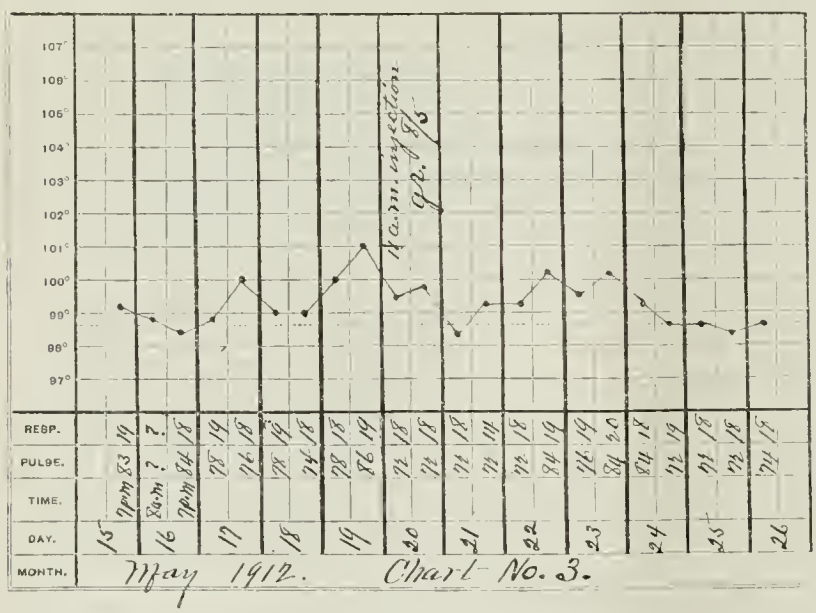
The diagnosis in the above cases was made on

the clinical symptoms, remittent fever, slow pulse rate in relation to temperature, and the presence in the urine of a motile bacillus.

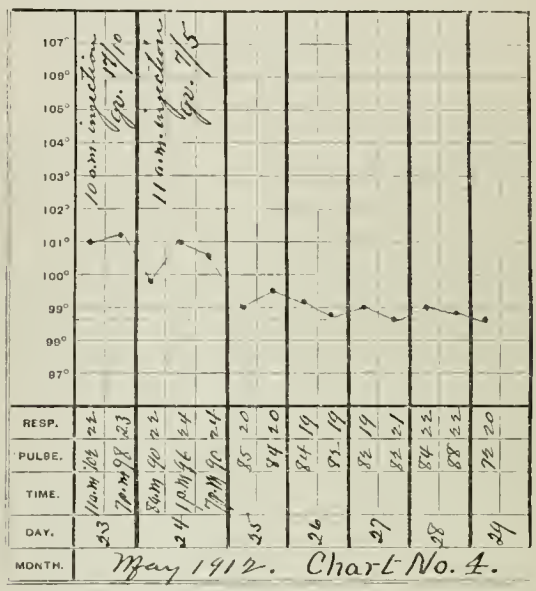
*Vincent's Angina.*—Case XLI.—Admitted May 15, 1912, with diagnosis of tonsillitis. $MgSO_4$ gm.



30 (ʒi) acetphenetidin, quininæ et salol āā gm. 0.13 (gr. ii.) every two hours, solution $AgNO_3$ (15%) applied to tonsils twice daily and Dobell gargle every hour. Up to May 19 the local lesions grew worse; on this date the silver solution was discontinued, pure iodine being substituted. May 20—Much worse, both tonsils presented deep eroded ulcerations, stained smears from which showed *Spirochetæ vincentii*. All previous treatment discontinued. 11 A.M., injection mercuric succinimide gm. 0.104 (gr. 8/5). May 21—Marked improvement. See Chart No. 3. By the 24th the local lesions had healed and on the 26th he was sent to duty.



*Lymphangitis.*—Case XLII.—Admitted 8:15 A. M., May 23, 1912. Infection by unknown organism which entered through a slight scratch made by point of bread knife on tip of left little finger May 21. States that upon going to bed on the night of May 22, was feeling perfectly well, but was awakened early in the morning of the 23d by severe pain in the left hand, forearm, and arm. These members were much swollen, very painful, and tender, all the superficial lymphatics were thickened, cord like, and bright red, the axillary glands were enlarged and tender. Temperature 101°, pulse 102, respirations 22. White count 25,120. Bed. $MgSO_4$ gm. 30.0 (ʒi). 10:30 A.M., injection mercuric succinimide gm. 0.110 (gr. 17/10). May 24—Markedly improved, arm perfectly comfortable, white count 10,800. May 25—Practically well. May 28—Injection mercuric succinimide gm. 0.078 (gr. 6/5) given as a precautionary measure. May 29—Discharged to duty. See Chart No. 4.

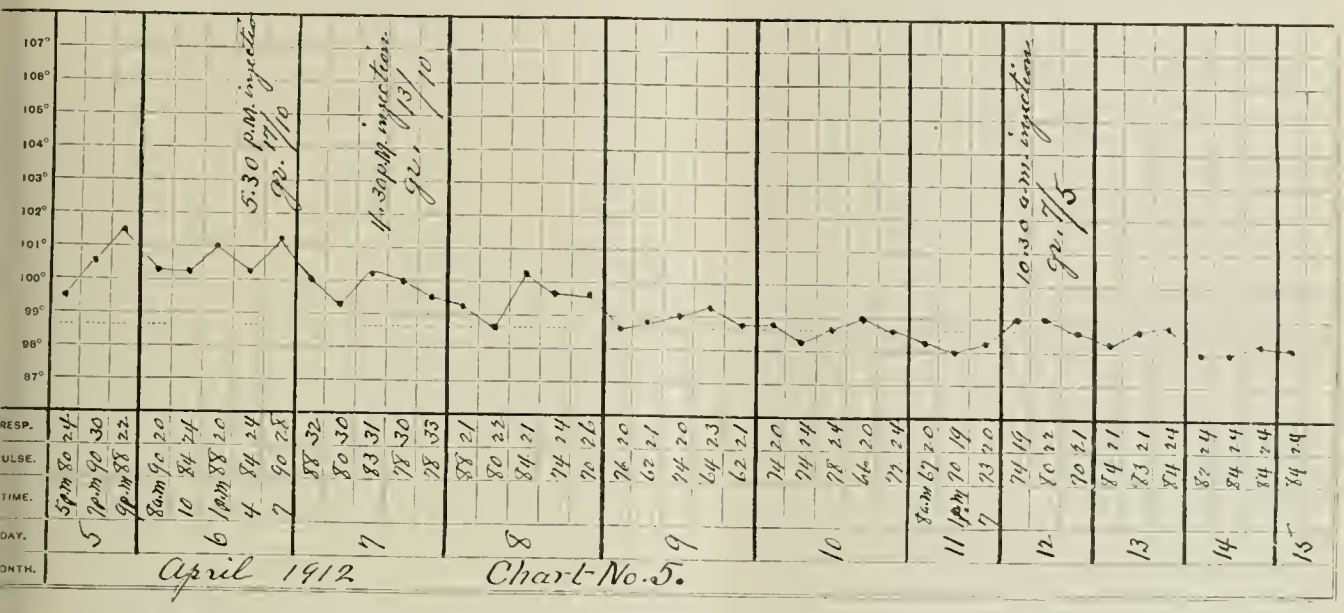


Case XLIII.—Admitted June 21, 1912, lacerated wound of palm of left hand, sustained at loading drill. Wound cleansed, wet $HgCl_2$ dressing applied, forearm in sling. Did well until the 24th, when he presented himself complaining of severe pain extending to axilla, which had kept him awake all the previous night. Hand considerably swollen and wound inflamed. 11 A. M., injection mercuric succinimide gm. 0.091 (gr. 7/5). June 25—All pain, tenderness, and swelling disappeared. Wound healed without further trouble. Discharged to duty June 30.

*Bronchopneumonia.* — Case XLIV — Admitted 8:15 A.M., April 5, 1912. Complaint: severe pain in lower left lobe. Temperature 99.6°, pulse 80, respirations 24, physical signs of old infiltrative process at right apex. Bed. $MgSO_4$ gm. 30.00 (ʒi), during the day developed cough. April 6 — Worse, during morning the sputum became profuse and intermittently rusty, both lower lobes presented the physical signs of bronchopneumonia. Sputum positive for pneumococci. White count 11,000. 5 P.M., white count 15,000. 5:30 P.M., injection mercuric succinimide gm. 0.110 (gr. 17/10). April 7—About the same. $MgSO_4$ gm. 30 (ʒi). 10 A.M.,

white count 16,000. 4 P.M., white count 14,240. 4:30 P.M., injection mercuric succinimide gm. 0.084 (gr. 13/10). April 8—Much improved; moderate mercurialism, abdominal pain, diarrhea, and gingivitis. Opii. pulv. gm. 0.016 (gr. ¼), potassium chlorate mouth wash. White count, 13,000. Convalescence established, which was uneventful. See Chart No. 5.

CASE L.—Reported October 27, 1912. Complaint: severe pain in lumbar region and in bladder, with marked vesicle tenesmus. Had gonorrhea in February, 1911. Urine contains pus and gonococci. October 28—Injection mercuric succinimide gm. 0.098 (gr. 1½). October 29—Marked improvement. October 30—Injection mercuric succinimide gm. 0.065 (gr. 1). October 31—All symptoms



*Furunculosis.*—The four following cases had had repeated outcroppings of boils extending over a period of from four to six months.

CASE XLV.—June 9, three boils incised, drained, and dressed. June 11, two additional boils incised and dressed. June 12, two more incised and dressed. June 13, three new boils developing. 11 A.M., injection mercuric succinimide gm. 0.104 (gr. 8/5). June 14—New boils aborted, pains and tenderness disappeared. June 17—No new outcropping. To duty.

CASE XLVI.—June 20, reported with nineteen boils of moderate size distributed over the inner surfaces of both thighs. Injection of mercuric succinimide gm. 0.104 (gr. 8/5). All boils aborted, no further outcropping. June 22—Injection gm. 0.065 (gr. 5/5) as precautionary measure.

CASE XLVII.—July 25, 1912. Ten boils of moderate size distributed over forearms. Injection mercuric succinimide gm. 0.091 (gr. 7/5). June 26—All pain and tenderness disappeared. June 28—One new boil developed on left side of face—injection mercuric succinimide gm. 0.084 (gr. 13/10). Aborted, no further outcropping.

CASE XLVIII.—Reported July 25, 1912. Six fairly good sized boils. Injection mercuric succinimide gm. 0.091 (gr. 7/5). June 26—Practically aborted, all pain and tenderness disappeared excepting in one boil on left knee. June 27—Cured.

*Gonorrheal Cystitis.*—CASE XLIX—Reported August 30, 1912. Complaint: pain in the bladder with marked vesicle tenesmus; these symptoms had followed apparent recovery from an attack of gonorrhea some three months prior to his present condition. Urine contained considerable amount of pus, and was positive for gonococci—injection mercuric succinimide gm. 0.098 (gr. 1½). August 31—Marked improvement. September 1—Injection mercuric succinimide gm. 0.065 (gr. 1). September 3—All symptoms disappeared. Cured.

about disappeared. Slight gingivitis. November 2—Injection mercuric succinimide gm. 0.065 (gr. 1). November 3—To duty. Cured.

*Gonorrheal Arthritis.*—CASE LI.—Reported August 22, 1912, with rheumatic pain in right knee joint, which developed some two years ago, following an attack of acute gonorrhea, since which time it has given him constant trouble. Injection mercuric succinimide gm. 0.098 (gr. 1½). August 23—Marked improvement. August 24—Injection mercuric succinimide grm. 0.065 (gr. 1). August 25—All pain disappeared and it has not returned up to date.

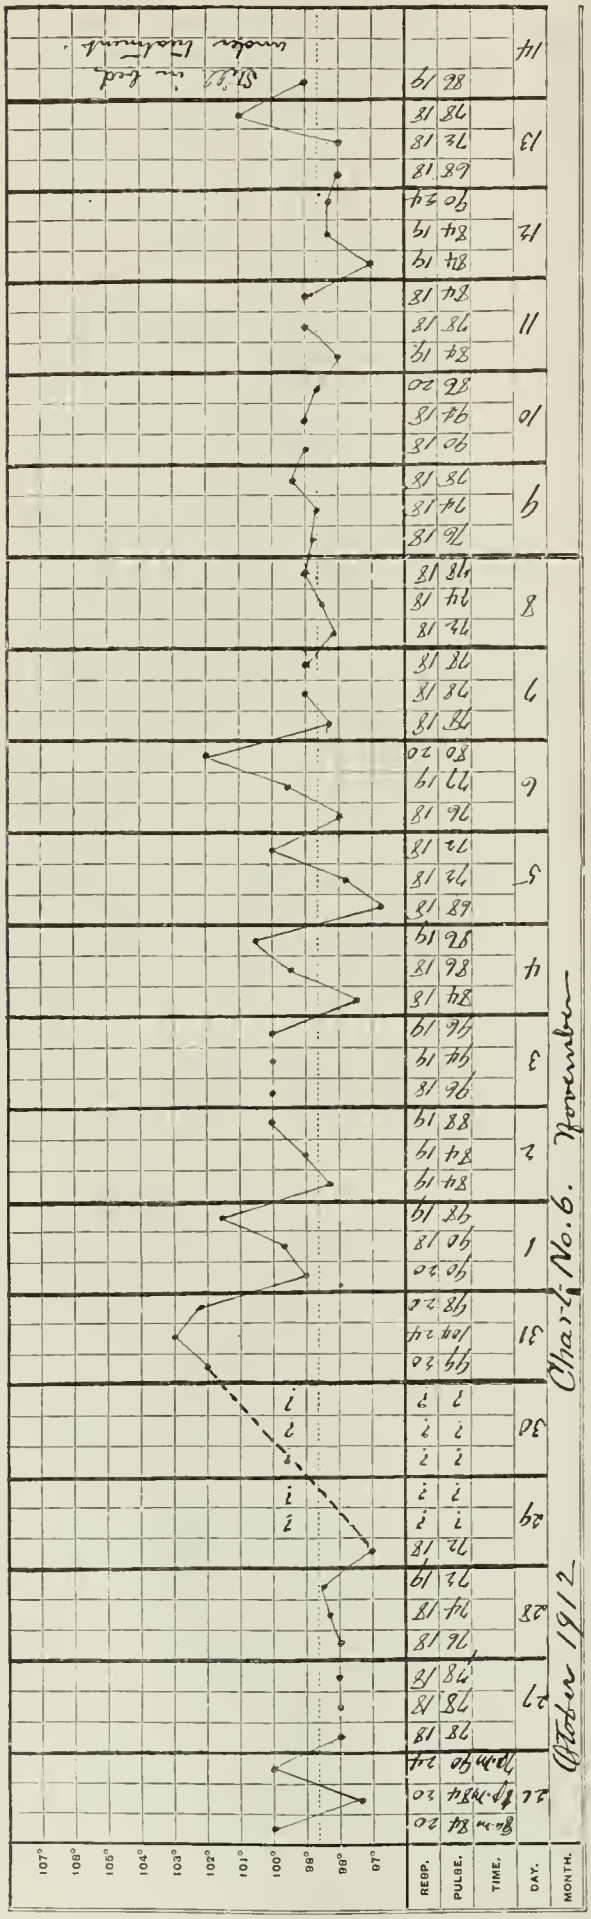
The following cases, thirty-two, treated by mercurial injections, out of some forty odd infections, represent an acute infectious disease caused by an atypical colon bacillus. In nearly all, the disease began suddenly being ushered in by a mild chill, followed by temperature of an intermittent type, with a daily range from subnormal to 102-103° and several times reaching 105°. The pulse from 85 to 104, being slow in relation to temperature. Headache and painful joints were common. The mentality bright. The white count was low, ranging from 3,000 to 6,000. Three types presented:

Pulmonary, in which there was severe paroxysmal cough, profuse purulent expectoration, which at times was purulo-sanguinous, associated with severe pains in the involved lung, and at times with inflammation and ulceration of tonsils and pharynx. These cases gave rise to higher temperatures.

Abdominal, in which there was somewhat obstinate constipation associated with colicky abdominal pain, usually in the gall-bladder region.

Genitourinary, in which some part of this tract was involved, giving rise to the usual symptoms produced by an acute inflammatory process of the organ infected.

The organism, an actively motile bacillus, Gram negative, was found in the urine of every case, in



the blood of sixteen cases examined, in the sputum of pulmonary cases, in tonsillor secretions and exudates, and in the pus from the one subcutaneous abscess noted. Out of five cultures made from the blood specimens of five cases, four were positive for this organism. Numerous cultures from the urines and other fluids and exudates were positive. The blood cultures and a number of urine cultures were sent to the laboratory of the U. S. Naval Medical School, Washington, D. C., for identification, one urine culture was sent to Professor Rosenberger, Jefferson Medical College, Philadelphia, Pa.; they reported "an atypical colon bacillus." I desire to express my thanks to Dr. Rosenberger, Dr. Stitt, U. S. N., and Dr. Clark, U. S. N., for differentiating this organism.

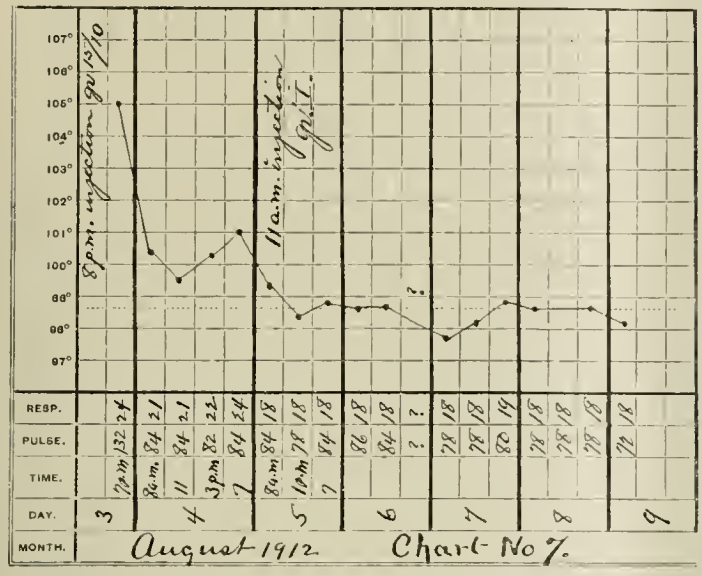
*Pulmonary Type*—(20 cases) 52-72: Case (*a*)—Reported as showing the course of a mild infection treated symptomatically, no mercurial injections having been given. Admitted October 26, 1912, complaining of sore throat, slight pain in right chest and slight cough associated with painful joints and malaise. The pharynx and tonsils were swollen and congested. Bed. $MgSO_4$ gm. 30 (℥i). Quinine and salol āā gm. 0.130 (gr. ii.) every two hours. Tr. iodine applied locally to pharynx and tonsils twice daily, Dobell's gargle every hour. Improved (see Chart No. 6), and was discharged to duty October 29. Readmitted 7 A.M., October 31, saying that he had not felt well since returning to duty, and making the same complaint as originally, excepting that all symptoms were worse. The same treatment was prescribed but without results. Cultures made from urine was positive for atypical *B. coli*. Quinine was given in moderate doses, urotropin gm. 0.648 (gr. x.) every three hours, various local applications were made, a tonic of iron and arsenic was tried.

Case (*b*)—Admitted August 3, 1912. Complaint: Profound malaise, painful joints, slight cough. Temperature 105°, pulse 122, respirations 24, see Chart No. 7. Bed. $MgSO_4$ gm. 30.0 (℥i). Urine and blood positive for atypical *B. coli*. 8 P. M., injection mercuric succinimide gm. 0.098 (gr. 1½). Immediate improvement. August 5, feels perfectly well, convalescence established. 11 A. M., injection mercuric succinimide gm. 0.065 (gr. i). August 8: Convalescence continues, blood showed a few motile bacilli. August 9: Blood negative for motile bacilli. Discharged to duty cured.

Case (*c*)—Reported July 3, 1912, complaining of headache, severe right-sided abdominal pain, just below the costal margin. Moderate cough and mucopurulent expectoration. Urine positive for motile bacilli. Temperature 103°, pulse 88, respirations 24, see Chart No. 8. 4:30 P. M., injection gm. 0.098 (gr. 1½). July 4, feels better, but cough is severe, profuse frothy purulent sputum. 3:30 P. M., injection mercuric succinimide gm. 0.078 (gr. 6/5). July 5, about same. July 6, marked improvement. July 9, sputum contains large numbers of motile bacilli, injection mercuric succinimide gm. 0.052 (gr. 4/5). From this point on patient improved rapidly. July 11, injection mercuric succinimide gm. 0.065 (gr. i). July 12, convalescent, cough and sputum disappeared. July 18, injection mercuric succinimide gm. 0.065 (gr. i) given as a precautionary measure. July 22, discharged to duty. This was one of two cases in which the fever was of remittent type.

Case (*d*)—Admitted October 20, 1912; complaint,

severe cough, profuse expectoration and malaise. Temperature 101.8°, pulse 116, respirations 20. Urine positive for motile bacilli. Symptomatic treatment, salol gm. 0.324 (gr. v) and codein gm. 0.016 (gr. ¼) every two hours. Condition remained unchanged until the morning of the 25th, when all

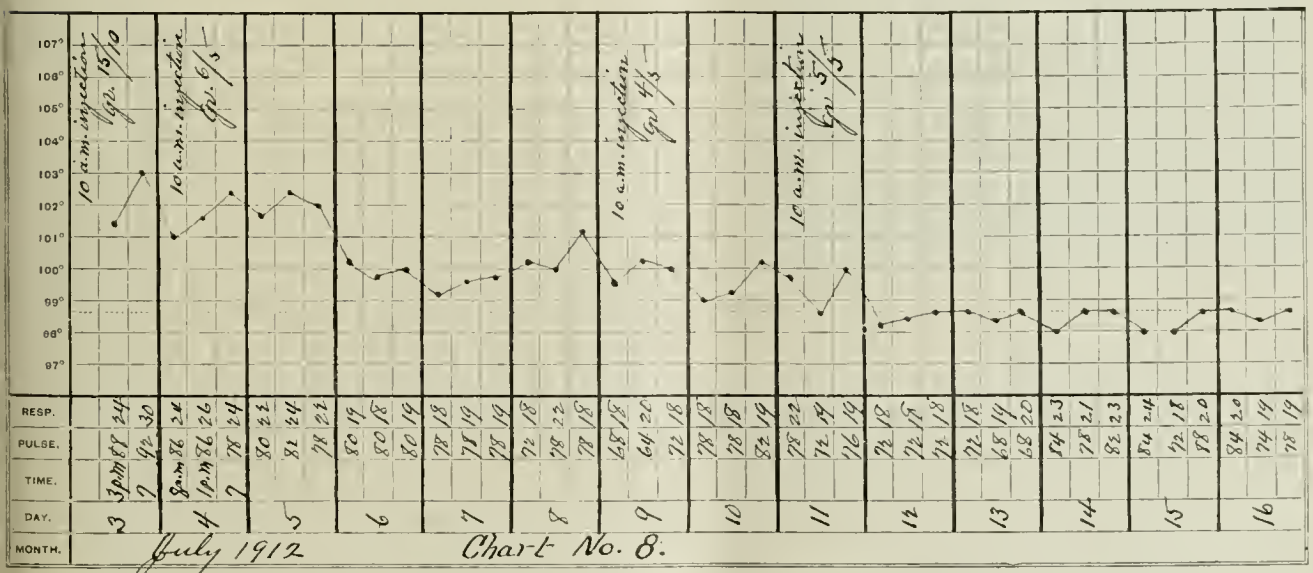


symptoms were aggravated, and a most severe pain developed in the right chest. Temperature 104°, pulse 84, see Chart No. 9, 10:30 A. M., injection mercuric succinimide gm. 0.098 (gr. 1½). October 26, marked improvement. October 29, injection mercuric succinimide gm. 0.065 (gr. i.). Cough and expectoration disappeared. November 2, injection mercuric succinimide gm. 0.065 (gr. i.). November 5, discharged to duty.

*Abdominal Type*—(4 cases), 73-76: All reported with severe colicky pain over the gall-bladder region, temperature about 100 to 100.5°, and more or less obstinate constipation, purgatives and other treatment administered symptomatically afforded no relief, all were promptly cured by one or two injections.

c.c. of urine in 24 hours, specific gravity 1000, considerable albumin, fatty and granular casts, renal epithelium, blood cells, and a moderate number of motile bacilli. 4 P. M., injection mercuric succinimide gm. .091 (gr. 7/5). June 15, edema of face and legs much less, passed 450 c.c. urine during 24 hours. Developed rather severe mercurialism, marked gingivitis, severe abdominal pain, purging, and rectal tenesmus. June 16, much better, passed 800 c.c. of urine, specific gravity 1010, trace of albumin, a few fatty and granular casts and a few red blood cells and motile bacilli were present. Bilateral hydrocele developing. June 18, much improved, feels quite well. June 19, total amount of urine 1,000 c.c. June 20, 1,000 c.c. urine, specific gravity 1006, slight trace of albumin, negative for casts. 2 P. M., injection mercuric succinimide gm. 0.052 (gr. 4/5). June 21, mecurialism, patient evidently having an idiosyncrasy for the drug. June 22, improved, 1,200 c.c. of urine passed during the 24 hours. June 24, 1,400 c.c. urine passed, specific gravity 1006, negative for casts, very few motile bacilli present. Mercurialism disappeared. June 29, complained of soreness in buccal surface of left cheek, small area moderately indurated. July 1, small ulcer developed in this area. July 2, well-developed ulcer about the size of a quarter. Fresh secretion from this ulcer showed moderate number of motile bacilli, stained smear (India ink), a number of spirochetes. Owing to this idiosyncrasy, mercury was not injected. The ulcer was painted with iodine twice daily and hydrogen peroxide mouth wash prescribed and an iron tonic administered. There was no further change in the condition of the kidneys. On July 10 he was transferred to the U. S. Naval Hospital, Newport, R. I., the ulcer healed, and his general condition apparently much improved. I have heard indirectly that he died some ten days following his transfer.

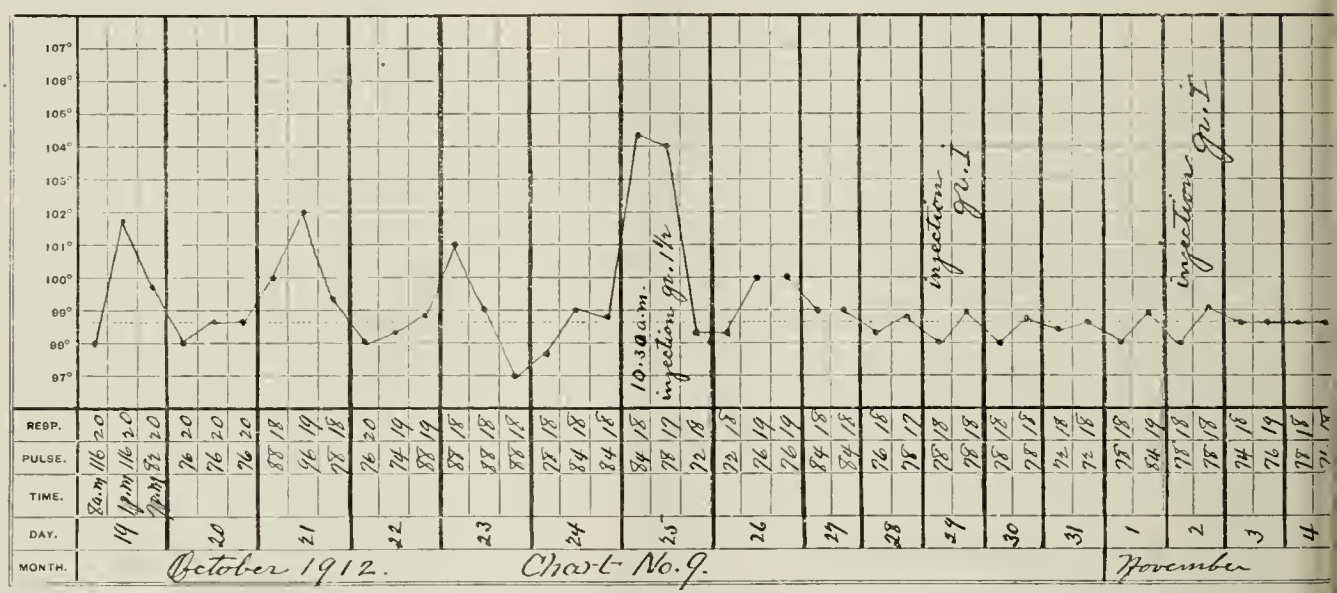
Case (*f*)—Reported June 12, 1912, complaining of nausea and headache, lower eyelids, feet, and



*Genitourinary Type*—(8 cases), 77-84: Case (*c*)—Admitted June 13, 1912. Complaint, pain in the back and profound lassitude and inability to urinate. His face and legs, edematous. Bed. $MgSO_4$ gm. 30.0 (℥ i). Diuretics. June 14, passes 250 ankles markedly edematous. Temperature 100°, pulse 84, respirations 24. Bed. $MgSO_4$ gm. 30.0 (℥i) Potassium acetate gm. 1.324 (gr. xx.) every three hours. July 13, about the same; 24 hours' urine 200 c.c., containing a large amount of albu-

min, coarse granular and hyaline casts, renal epithelium, blood, and numerous motile bacilli. Caffeine citrate gm. 0.032 (gr. ½) every 3 hours; 300 c.c. of water every hour, in addition pilocarpine gm. 0.008 (gr. ⅛) at 1.30 P. M. June 14, total amount of urine voided 300 c.c. All former treatment discontinued, injection mercuric succinimide gm. 0.091 (gr. 7/5). June 15, much improved, edema rapidly disappearing, voided 600 c.c. urine. June 16, much better, edema disappeared; 800 c.c. of urine voided. Specific gravity 1012, slight trace of albumin present, Hyaline casts, epithelium and blood disappeared. A few granular casts. Motile bacilli very numerous; 1 P. M., injection mercuric succinimide gm. 0.078 (gr. 6/5). June 17, improved; 1,000 c.c. of urine passed. June 19, feels perfectly well, urine contains slight trace of albumin, and a few motile bacilli. June 20, 1,500 c.c. of urine passed, specific gravity 1020, negative for albumin and motile bacilli. June 21, injection mercuric succinimide gm. 0.065 (gr. i). June 23, urine normal in amount and color, specific gravity 1014, free from albumin, casts, and motile bacilli. June 27, to duty, cured.

Case (*j*)—Reported August 30, 1912, complaining of pain in the bladder and back and marked vesicle tenesmus. Urine contained large numbers of motile bacilli and considerable pus; 10 A. M., injection mercuric succinimide gm. 0.098 (gr. 1½). August 31, marked improvement. September 2, injection mercuric succinimide gm. 0.065 (gr. i). September 4, has felt perfectly well since last injection. September 25, reported complaining of same symptoms noted above. Motile bacilli again present in urine, injection mercuric succinimide gm. 0.098 (gr. 1½). September 27, gm. 0.078 (gr. 6/5). September 30, gm. 0.065 (gr. i.), following which he had no further trouble.



Case (*g*)—Reported at 7.15 P. M., August 8, 1912, complaining of severe pain in both kidneys radiating down the ureters. Bed. $MgSO_4$ gm. 30.0 (℥i), urotropin gm. 0.648 (gr. x.). August 9, no change, urine contained numerous motile bacilli; 11 A. M., injection mercuric succinimide gm. 0.091 (gr. 7/5). August 10, symptoms nearly disappeared. Slight gingivitis. August 10, condition cured. Gingivitis continues, potassium chlorate mouth wash. August 14, to duty.

Case (*h*)—Reported July 3, 1912, with swollen, tender, and painful right testicle, pain extending up the cord. Urethra normal and no history of injury. Urine contained moderate number of motile bacilli; 11 A. M., injection mercuric succinimide gm. 0.098 (gr. 1½). July 4, testicle and cord normal, pain entirely disappeared. To duty.

Case (*i*)—Admitted by the junior medical officer of the ship August 9, 1912, with severe pain in right abdomen, no diagnosis. Bed. $MgSO_4$ gm. 30.0 (℥i) and Dover's powder and quinine āā gm. 0.162 (gr. 2½) t.i.d. prescribed. August 10, $MgSO_4$. August 12, no change until 7.15 P. M., when he complained of severe pain in both spermatic cords and testicles. August 13, condition the same. Urine negative for motile bacilli. Blood positive for motile bacilli, phagocytosis of these organisms well seen. August 14, pain in cords and testicles much worse, suffered intensely all previous night; 10 A. M., injection mercuric succinimide gm. 0.098 (gr. 1½). August 15, marked improvement, quite comfortable. August 16, the same, injection mercuric succinimide gm. 0.065 (gr. i). August 17, about well. August 22, cured, to duty.

Case (*k*)—Reported October 21, 1912, after having been at his home for a week, bringing with him a certificate from his family physician stating that he had been under his treatment for lumbago during the previous five days. Complaint, pain in the back and vesicle tenesmus. Bed. Urotropin gm. 0.648 (gr. x.) every three hours. October 22, condition the same. The urine contains a large amount of pus, negative for albumin, casts, and motile bacilli. Treatment continued. October 23, no change in condition. Bouillon tube inoculated with 2 c.c. of urine. Urotropin continued. October 24, culture almost pure, motile bacilli. Pain in back very severe, passes urine involuntarily. All previous treatment discontinued; 10 A. M., injection mercuric succinimide gm. 0.098 (gr. 1½). October 26, marked improvement, nearly free from pain. October 27, 10 A. M., injections mercuric succinimide gm. 0.078 (gr. 6/5). October 28, about well. October 30, to duty, cured.

Case (*l*)—Patient reported October 23, 1912, complaining of severe pain in the left loin and of vesicle tenesmus. Urotropin gm. 0.648 (gr. x) every three hours prescribed. This was continued

until October 28, when all symptoms were very much aggravated. Urine showed pus and motile bacilli. Bed. 10.30 A. M., injection mercuric succinimide gm. 0.098 (gr. 1½). October 29, marked improvement. October 30, improved. Injection mercuric succinimide gm. 0.078 (gr. 6/5). November 2, about well. Injection mercuric succinimide gm. 0.065 (gr. i) given as precautionary measure. November 5, no further trouble, discharged to duty, cured.

From the "Paris Letter" of the MEDICAL RECORD of recent date, I quote the following: "An interesting discussion took place recently at a meeting of the Société de Chirurgie on the treatment of infection by intramuscular injections of mercury. Souligoux related his experience with this method in the treatment chiefly of puerperal infection. He injected daily for seven days a solution of 1 cg. each of cyanide of mercury and stovaine in 1 c.c. of distilled water. Of 144 patients so treated, the author lost but three, and on the strength of this showing urges the use of mercury in all cases of systemic infection, the only contraindication being renal insufficiency."

## PERSONAL OBSERVATIONS WITH SUSPENSION LARYNGOSCOPY.

BY WOLFF FREUDENTHAL, M.D.,

NEW YORK.

WHEN a gynecologist or general surgeon starts out to remove a 10-lb. tumor from any part of the body he is certain that he will get it. But when a laryngologist is about to extract a little bit of a fibroma from the vocal cord he never works with positive knowledge of success. Skill and experience go a great ways, but here the psychology of the patient often plays an unpleasant part. In a number of instances the application of cocaine has an opposite effect from that desired, the patient becoming very nervous from the inability to swallow and a muffled feeling in his throat. Everybody with large experience has seen such cases. General anesthesia is impossible.

Other affections of the larynx are localized at such places that they cannot be reached well; for example, ulcerations in certain places causing dysphagia and finally odynphagia. Whether a patient dies from a large tumor in the abdomen or small ulcers in the larynx is equally important, since it is a loss to humanity.

It was therefore not more than natural that laryngologists for a long time in the past looked for another method to make the larynx more accessible. The first was Kirstein with his autoscopy. That was given up. Then came the direct laryngoscopy of Killian. No doubt that method constituted a decided advance and occasionally it worked well, but altogether it was not satisfactory.

Then Killian himself worked for several years on a new idea, the result of which is "Suspension Laryngoscopy." Before describing this novel way of rendering the larynx accessible to our vision and instruments it may be proper to remind the reader that in 1907 von Eicken* and Gerber almost simultaneously published their observations on hypopharyngoscopy and pharyngo-laryngoscopy, respectively. By means of a hook introduced into the larynx and drawn forward, not only was its interior exposed to view, but the sinus pyriformes and the upper portion of the esophagus as well. In the writer's experience, however, this method was only rarely effective and apparently has been forgotten. Although in exceptional instances the above picture was visible, even then the method proved impracticable from an operative standpoint.

The new method of Killian, *i.e.* suspension

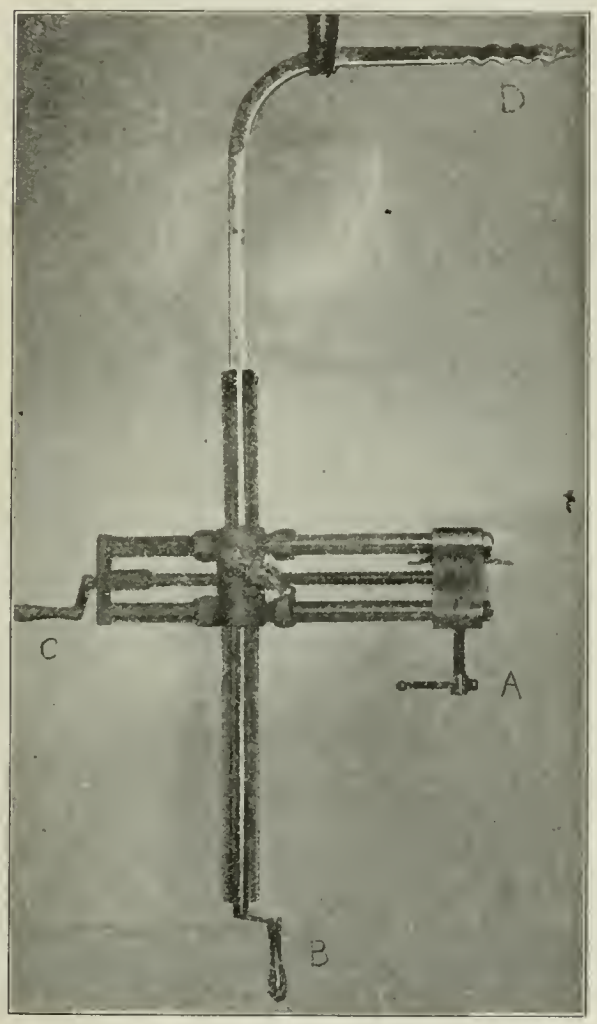

FIG. 1.—The stand for use in suspension laryngoscopy.

laryngoscopy, is both easy to learn and of great practical value. Killian hit upon this invention through a mere coincidence. In order to afford a draftsman a good view of the interior of the larynx he had a cadaver hung up by the lower jaw. Afterwards the idea struck him that this procedure might be possible on the living subject. Fortunately he found a good subject, and after much arduous work brought the method to its present perfection.

The instrumentarium necessary for suspension laryngoscopy consists of the following: An operating table, a so-called gallows or stand, and the hook spatula.

*See Frankel's Archiv für Laryngologie, Vol. 19, 1907, pp. 213, 336.

Any operating table that can be straightened out will be suitable for this work. It is best to have one that is not too low or one that can be raised to the desired height. The gallows or stand (Fig. 1) is screwed on to the operating table at the right side of the patient. It consists of an iron bar bent nearly at a right angle, is held by a strong screw (A) attached to the table and can be moved easily by means of cranks upward and downward (screw B), and forward and backward (screw C). It is important that all these screws and cranks move easily, *i. e.* without jerking. The horizontal part of the bar is hollowed out in several places (D) in order to receive the third part, viz., the hook

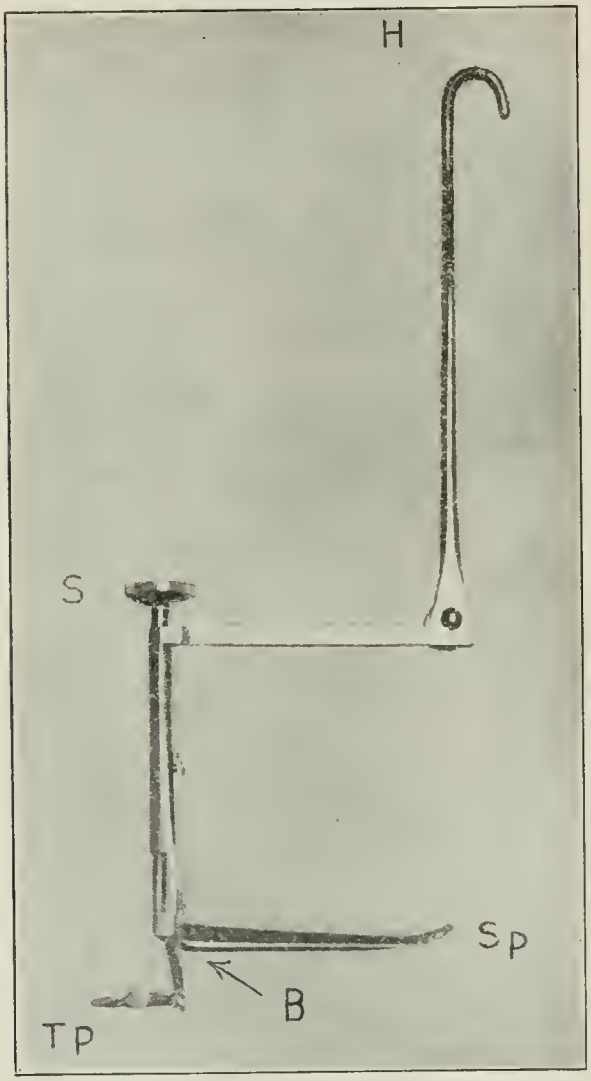

Fig. 2.—The hook spatula; H, hooks; S, screw; Sp, spatula; B, bridge; Tp, tooth plate.

spatula, so called by Killian (Fig. 2). This again really consists of three parts: (*a*) the handle, (*b*) the tongue holder, and (*c*) the mouth gag. The handle, according to the original device, is a straight hook 32 cm. long, which is attached to the stand. Connected with it is a tongue depressor, a modified Fränkel spatula (Sp.). It is hollowed out so that the cross section is "V" shaped. Since it is not used to depress the tongue, but to hold it up, I prefer to call it the tongue holder. Attached to the handle is also the mouth gag, which has a plate for the upper teeth (T. P.) and can be opened or narrowed down by means of screw S to suit the individual case. It is open to the right to give the operator space for his instruments.

The writer uses a modification of this handle as published in the *Berl. klin. Wochensch.*, p. 1331, 1912, by Dr. Albrecht. Instead of the hook being one straight line, Albrecht bent it at right angles at a certain distance from the spatula. It runs parallel (*d e*) to and extends as far as the tongue spatula (*c b*). To it is now attached the hook, so that schematically it looks like this:

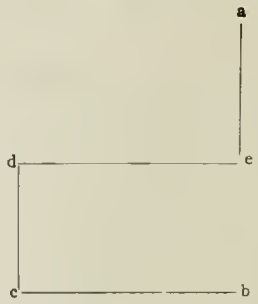

Fig. 3.

The advantage derived from this modification is that the instrument has a tendency to push itself into the interior of the larynx, rather than to slip out. Details of these theoretical deductions, which have since proved to be practical, can be seen in the article cited above.

After having thus described as briefly as possible the instrumentarium, we now come to the operative procedure itself, and shall discuss, first:

*The Operation Under Local Anesthesia.*—Generally speaking, it may be said that the same rules hold good for suspension laryngoscopy as for bronchoscopy. Those patients who can open the mouth wide, have no incisor teeth, and can bend their head backwards with ease will make good subjects for a trial, while others, with short, thick necks, etc., will be difficult to examine. After thoroughly cocainizing the base of the tongue, the pharynx, epiglottis, and interior of the larynx with a 20 per cent. solution of cocaine, the patient is placed flat on the operating table. The stand or gallows having been attached to the table, the surgeon seats himself back of the patient, one assistant to his right and a nurse on the left to hold the patient's head. The nurse may be dispensed with, but occasionally is of much assistance. The patient is then placed so that his shoulders are on a line with the table, the head hanging down or being held by a nurse. The writer now proceeds somewhat differently from Killian, who attaches the tongue spatula to the gallows and then introduces the spatula standing. The writer is seated from the start, and under a good illumination by the Kirstein head light introduces the spatula slowly far back into the pharynx (the epiglottis is not always visible), while almost simultaneously the assistant adjusts the stand in a horizontal and vertical direction and hangs the tongue spatula in its place. Now the screw S is used to open wide the mouth, and the adjustment of the apparatus is completed (Fig. 4). The view now obtained is excellent. We see at once the interior of the larynx, more so especially, naturally, the posterior commissure; we see part of the trachea, the sinus pyriformes, the pharynx, and occasionally the upper portion of the esophagus. At the same time we have both hands free for operation and the larynx is absolutely open to us, *i. e.* there is no hook or tube in it to encroach upon its lumen. How valuable this is to the surgeon everyone will appreciate who operates by this method.

In order to remove certain diseased areas from

the interior of the larynx we simply resort to a double straight curette or any other suitable straight instrument, and this can be done as quickly, or more quickly, than I can put this in writing. I have done this repeatedly. At other times it is more difficult, but it is always easier than with the old method.

*The Operation Under General Anesthesia.*—In the case of timid patients, and where we expect to do a major operation, we give general anesthesia. Killian uses either the morphine-scopolamine narcosis or chloroform. In this country chloroform is considered by most anesthetists more dangerous than ether, and for that reason we have generally employed the latter. The introduction of the tongue spatula is somewhat more difficult under general anesthesia. When the patient is under the influence of the anesthetic the mouth gag is put into the right corner of his mouth, the tongue slightly withdrawn, and the spatula inserted. After the spatula is once fixed, the mouth gag is taken out. Thus far the writer has resorted to general anesthesia in only a few cases, since the majority could be operated upon with ease under a local anesthetic. It must be remembered that in order to eliminate the element of reflex action we must apply cocaine to the larynx even under general anesthesia.

Care must be taken not to put the patient's head too far backward; a mistake that is made by beginners just as frequently as in bronchoscopy. The introduction of the spatula is sometimes rather difficult, not only because the tongue occasionally gives a great deal of trouble, but the configuration of the teeth and mouth, etc., tends to add to the difficulties. If the patient does not hold his tongue up, but moves it in all directions, the best way to overcome this is to introduce the spatula from the side. The teeth also occasionally give us quite some trouble. I recall the case of Mrs. B., whom I examined for diagnostic purposes. She had a very marked bust, and besides there was only one incisor tooth in the upper jaw, from which the plate constantly slipped off, but finally we succeeded in attaching the instrument.

There are several advantages connected with this method. (1) We see parts which could not be seen otherwise. (2) Other parts, as neoplasms, for example, assume a different aspect. (3) It is easier for the patient and the physician to operate in this way.

Referring to the first, I would mention the anterior portion of the posterior laryngeal wall. This is easily brought to view. The writer has examined quite a number of tuberculous cases, and here we frequently have ulcerations, infiltrations, stalactite-like excrescences, etc., in that region. To remove these has always been a difficult, often an impossible, task. I believe that by this method a new era has been inaugurated; at least I feel that my surgical inactivity of the last few years in such cases has already undergone a radical change. We removed formerly portions of vocal cords and ventricular bands, with discouraging results after many years' experience. Now we are in a position to operate in the interarytenoid region and on the arytenoids as well. These cases often include incipient and primary conditions of laryngeal tuberculosis. Larger experience will show us the value of such procedures. One thing is positive, viz., that we are able to curette all ulcerations much more thoroughly than ever before. That evidently is a more efficient procedure than the application of lactic acid, nitrate of silver or even the galvanocautery point.

Secondly, by means of suspension laryngoscopy one sees tumors of the larynx, granulations, etc., in a different way, *i. e.* more bodily, if I may say so. The whole depth of a neoplasm can be judged better in cases of carcinomatous or other growths. The case of S. F. (Case IV) will best illustrate this point.

Thirdly, after a patient has once overcome the fear of being placed on an operating table the operation is more comfortable for him as well as for the physician. For the patient, because it is performed more quickly; for the physician, because a great deal of time and energy is saved. To be almost entirely independent of the patient's assistance is, indeed, a great step forward in the surgery of the larynx.

The most difficult part to see is naturally the anterior commissure. Very often the epiglottis slips off and hides that portion of the larynx. No matter how often you insert the tongue holder in certain cases, the epiglottis will slip off and prevent us from seeing and operating in the neighborhood of the anterior commissure. To overcome this, the writer has modified the spatula, a description of which will be published shortly.

Fig. 4.—The patient ready for operation, with the instruments in position.

It is evident that suspension laryngoscopy will be used mainly for tuberculous cases and papillomata of the larynx, especially in children, but there are a number of other conditions where the value of this method will be clearly shown. We would refer again to the case of Sam F. (Case IV), in which there was a web-like structure in the trachea, and would further mention cases of abscess of the larynx. You know how dangerous it is to open an abscess of the larynx in the sitting posture, and that accidents happen repeatedly. How much safer will we feel when we operate with the patient's head hanging downward and when we are assured that the contents of the abscess will drain downward, *i e.* into the nasopharynx. An extensive field in the removal of foreign bodies from the larynx is opened to us now. The question of tonsillectomy will be referred to later in this report.

Let me now quote a few cases operated on with the aid of suspension laryngoscopy:

Case I.—M. F. has suffered from tuberculosis of the lungs for about eight years and has a large mass of tuberculous infiltration, with an ulceration on the posterior wall of the larynx. Both arytenoids seemed enlarged (perichondritis). He had been seen by many colleagues of this city. The writer

also had him under treatment for quite a time, but it was impossible to get rid of the infiltrations. Even fulguration did not exert any beneficial effect, as it was not well tolerated by the patient. Since his pulmonary condition did not bother him he was naturally desirous of having his throat cured. On November 15, 1912, in the presence of a number of laryngologists who attended the Clinical Congress of Surgeons, quite a large piece was removed from the larynx. Part of the arytenoid had been caught and removed at the same time, but not the entire mass of granulations. Post-operative pain was very slight; no dyspnea. A false membrane formed over the site of operation, but soon disappeared. On December 20, 1912, the whole mass was curetted thoroughly, with very satisfactory result thus far.

Case II.—Mrs. Z., a very nervous and excitable woman, was suffering from tuberculosis of the lungs and ulcerations of the epiglottis and left vocal cord. She was curetted on November 8, 1912, as thoroughly as possible. The dysphagia disappeared to a great extent afterwards, and if it were not for the pain from the ulceration of the epiglottis that could not be reached she would have felt much better. Two weeks later a number of ulcers appeared, which, however, healed slowly under routine treatment.

We have examined and operated on five more tuberculous patients without any ill effect, and we mention the following case as a warning to others:

Case III.—Miss Bertha X., who was in the third stage of tuberculosis and was suffering from pulmonary dyspnea was sent from Bedford to New York for curettement of ulcers in the larynx. This was easily done under local anesthesia, but the patient refused to stay in the hospital over night. The following night an edema of the larynx developed and she suffered a great deal. She completely recovered, however, from the effects of the operation. This case should admonish to caution, since in every case of laryngeal tuberculosis a dangerous edema may set in after any operation. Patients with advanced tuberculosis naturally must be treated with greater care, and they should remain in the hospital at least over night in order to be safeguarded against possible suffocation.

Case IV.—Another case operated upon by me was that of Sam F., twenty-five years of age, who had had diphtheria four years previously, when he was tracheotomized. He felt perfectly well up to three months ago, when a slight dyspnea set in, which still exists. On laryngeal examination a grayish-looking web-like structure was seen below the glottis, which was surely the result of tracheotomy. We tried to remove this under local anesthesia by the suspension method, but did not succeed, as the patient was extremely timid. We succeeded, however, in examining the trachea, and to our great surprise saw a mass of granulation tissue on the anterior wall instead of the web seen before by ordinary laryngoscopy. The picture was so striking that we showed it to quite a number of physicians present. A few days later he was placed under general anesthesia. Before we started the introduction of the spatula or any other instrument, the patient became very blue in the face and apparently was becoming asphyxiated. No time was lost; tracheotomy was done in a hurry, but the patient did not breathe. Fortunately, we had Elsberg's insufflation apparatus on hand and inserted a rubber tube into the bronchus, connected this to the tank of the Elsberg apparatus and pumped pure air into the bronchi. Soon the patient was out of danger.

I mention this case for two reasons: Firstly, because the picture seen by the ordinary method was so entirely different from that seen under suspension, and, secondly, to express my opinion that it was only by resort to the Meltzer-Auer-Elsberg method that the patient's life was saved.

Case V.—Still another case was that of Robert F., who had a papilloma of the right vocal cord about in its center, which was easily removed by means of McCoy's forceps.

The last cases to be mentioned are six tonsillectomies. While at first it seemed difficult to reach the tonsils, a little experience showed us that in most cases where the mouth of the patient can be widely opened this difficulty can be easily overcome. Furthermore, we had to learn to work mainly from the right side of the patient, because on the other there is the bridge connecting the tongue spatula with the tooth plate. Besides, we again encountered difficulty with the tongue, but finally the idea occurred to me to introduce and attach the spatula sideways, and in that way the tongue was pushed to one side. When it is once attached in such manner it is not in our way and we can reach the tonsil easily. The benefit derived from this mode of operating on the tonsils is due to the fact that the blood flows down into the nasopharynx and we do not need any suction apparatus to get it out of our way, but can finish our work quickly, if the anesthesia is complete. But it must be left for future experience to decide this and other questions in connection with operations performed according to the new method. However, we are already able to state that it constitutes a valuable contribution to our laryngological technique, and there is no doubt that it will bear very good fruit in the near future.

1003 Madison Avenue.

## THE EFFECTS OF THE BEERLESS EXCHANGE ON THE MORALS AND HEALTH OF OUR SOLDIERS.

By L. MERVIN MAUS, Colonel, M.C., U.S.A.

CHIEF SURGEON, EASTERN DIVISION.

The daily press has recently attempted to enlighten the public on the moral and physical condition of the enlisted men of the army as a result of the beerless canteen or post exchange. It will be remembered that the sale of beer was interdicted in army posts by an act of Congress in 1901, and that an annual effort has been made for its restoration. No fair-minded person objects to an honest and unprejudiced discussion of a question which has become a national issue, but every patriotic citizen resents a controversy whose only line of argument consists in shameful denunciations of our soldiers in order to influence public opinion for legislative purposes. As a champion of the enlisted men of the army, with whom I have spent my life, I submit this article with the hope that it may in a measure right the great wrong already done to our country's brave defenders.

No one can properly discuss the canteen question without invading the wide field of temperance, which has become the most important sociological problem of the age. Apart from its bearing on the health and preservation of the human race, temperance has become a cold-blooded business proposition which is assuming the greatest importance in the commercial world. Professional and business men everywhere are beginning to learn that even

the mildest manifestations of the drink habit unfit men for the ordinary pursuits of life.

The spirit of the commercial world has changed entirely during the past generation, and employees are looked upon as business assets. Sympathy and sentimentality for the drinking element is fast dying out, and no one in the near future can expect consideration who handicaps himself mentally and physically through the deadening influence of alcohol. Hundreds of thousands of the most intelligent and alert young professional and business men of the country are voluntarily cutting out drinking because they have found that total abstinence is the only certain road to health and success in life.

Have not railroad companies prohibited alcoholic beverages, even beer among their employees? Is this not so with many street-car systems, factories, banks, schools, and colleges? A law has recently been passed at Albany making intemperance among chauffeurs a penal offence, in order to prevent the reckless loss of life and limb which results from drink. Many steamship companies require total abstinence among their navigating officers, and can anyone deny that the lack of this obligation among the officers has not been the indirect cause of more than one terrible disaster?

The statutes of the State of New York forbid the introduction or sale of any alcoholic drink in a State armory, which expresses the sentiments of the people in this great commonwealth in regard to the use of intoxicants among the state militia. It is also a well-known fact that in a community threatened with riot the first action of the authorities is to close the saloons. In order to promote good law and order in every self-respecting and God-fearing community saloons are closed on Sunday, election days and many of the holidays.

It has been stated that the War Department is contemplating issuing an order making total abstinence compulsory among army aviators. Flying, above all things, requires a cool head, clear eye and steady hand, conditions which are absolutely impossible with those who drink even moderately. Until the day of judgment no one will ever learn how many of the hundreds of aviators who lost their lives during the past few years have alcohol to blame for the tragedy.

The army and navy officer is an expert of the highest class and holds a position of the greatest responsibility, whether he is charged with the manufacture of battleships, arms and equipment, the purchase of supplies, caring for the health of the men, or commanding troops and dreadnoughts. Besides, he becomes a specialist and is entrusted with work or duty upon which the safety of the country frequently depends. It is my candid opinion that any officer of the army or navy who renders himself incompetent or stupid through drink during actual warfare might just as well enter into treasonable relations with the enemy and sell his country as did Benedict Arnold.

The commercial warfare which is engaging the great nations of the world and the spirit of unrest, as expressed by the recent wars in Europe and the Orient, makes it obligatory upon the United States to employ every known measure to promote the efficiency of our army and navy. The sentimental side of military life has been fading away ever since the days of knight errantry and the substitution of khaki and olive drab for gold lace and feathers. The art of warfare has become a keen business proposition which requires science, skill, alertness and preparation of the highest order.

The army and navy is a great national corporation, which concerns our country so vitally that the American people are not willing to have moral questions, affecting the efficiency of our soldiers and sailors settled by those who favor drinking and who believe handy beer a universal panacea against intemperance and diseases of vice. Would it be considered a sane business proposition for any corporation to employ ordinary workmen in competition with similar companies which employ skilled labor?

Those of us who have studied the alcoholic question in military circles will remember that the policy of the War Department has undergone a number of changes with regard to the army saloon since the great Civil War of 1861-1865. From that period until 1881 no restraint was placed on the sale of alcoholic drinks in army garrisons and drunkenness was correspondingly common. A feeble wave of temperance passed over the country during the administration of President Hayes, which was stimulated by the lofty stand of his courageous wife, and in 1861 prohibition was enforced throughout the army.

A slight reaction occurred in the policy of the War Department in 1885, whereby the sale of light wines and beer was permitted, first in company canteens, and finally in the post exchange, where it remained until abolished by an act of Congress in 1901. Those of us who attended the funeral of the army saloon hoped that its interment was final, but, unfortunately, like Banquo's ghost, its disturbing spirit makes its perennial bow to the American Congress and won't be downed.

In studying the canteen problem, I find the army divided into three distinct parties: the Progressives, the Reactionaries, and the Indifferents. The Progressive Party may safely be estimated at ten per cent. of the officers and enlisted men; the Reactionaries at five per cent., and the Indifferents at eighty-five per cent. The Progressives believe that the best interests of the soldier would be subserved through the beerless exchange. The Reactionaries feel that beer and light wines are essential to the soldier's health and moral welfare, while the large army of Indifferents have never formulated any views on the subject and are not interested in the matter.

Among the advocates of the canteen are men and women who do not believe moderate drinking is either harmful or opposed to the true spirit of temperance. The scientific study of moderate drinking on the human system has taught us that there can be no compromise in the great battle now being waged against alcohol. The increasing use of cocktails, high-balls, and ciragettes among the young men and women of the country has become a great curse to society, and, if continued, will result in the racial degeneracy of America as it has in France. Besides the vicious tendencies of the age resulting from tippling, the lack of religious training at home and school, and the voluptuous step of immoral dances are becoming a menace to the youth of our country.

In their complaints against the law of 1901, abolishing the canteen, its advocates charge the army with increasing intemperance and diseases of vice. Specifically, they state that the anti-canteen law has, (1) increased sickness in the army; (2) increased

its non-efficiency rate; (3) increased drunkenness; (4) increased desertions; (5) increased diseases of vice; and (6) resulted in the establishment of saloons and brothels in the vicinity of the posts.

In reply to the charges, it is only necessary to quote from the article by the Surgeon-General with reference to the health of the army, which was published in the *Continent,* January 18, 1912. He states that "The statistics do not show that the absence of beer from the canteen has increased the admissions to sick report or the ratio of constantly sick." The last report from the Surgeon General's Office, 1912, informs us that the health rate of the army was never better. It states that "The ratio (admissions for sickness) for 1911 was 769.44 per 1,000 of mean strength; for the previous year 766.06, * * * "This is the lowest admission rate for diseases for any year in the history of the army except that for the year 1910." The lowest admission rate during the canteen period was 10.90 per 1,000, while the average rate during the canteen years, 1888-1898, was 12.46 per 1,000. The parentheses are mine and are used for explanatory purposes. It seems singular that any army officer would make statements contrary to the above figures from the report of the Surgeon General of the Army, as has been reported recently in the newspapers.

The constant non-efficiency rate of the army has also been greatly lowered during the past few years, which shows an exceedingly healthful condition of the army under the beerless canteen. The rate from 1888 to 1898, during the flourishing days of the canteen, ranged as high as 42 per 1,000. The report for 1912 shows the rate 33 per 1,000.

Alcoholism, which caused an admission rate as high as 46 per thousand during the canteen period, has been reduced under a beerless canteen in 1912 to 20 admissions per thousand, a reduction of more than 50 per cent., which speaks well for army prohibition.

The rate of desertions in the army has also gradually declined since the abolishment of the canteen until it reached in 1911 the lowest rate on record in 90 years. The above statements are based on official reports from the War Department, and I challenge anyone truthfully to refute them.

These four great triumphs alone would fully vindicate the wisdom of Congress in repealing the canteen in 1901, if nothing more, but let us analyze the fifth and sixth indictments against the beerless exchange. It has been frequently stated that the sanitary conquest of preventable diseases which resulted from our war with Spain has fully justified the financial outlay in waging it, and the sacrifice of our men. The splendid triumphs of the Yellow Fever Board in Cuba, which has banished that dread disease from the Western hemisphere, the emancipation of Porto Rico from the devitalizing influences of hookworm, the successful malarial crusade in Panama, and the regeneration of Manila and the Philippines through scientific sanitation, makes us realize what preventive medicine has done for the world.

Until 1901 little or no attention was paid to diseases of vice in the army and fully two-thirds of the men afflicted with them received little or no official attention. The military records during the canteen period, and before that time, regarding diseases of this character, were very incomplete, and it is the belief of medical officers who served during that period that scarcely one-third were recorded. Since the Spanish War, great attention has been awakened to diseases of vice, and inspections instituted which have resulted in their apparent increase. I believe that diseases of this class are less in the army today than ever in the history of the canteen period.

The recorded rate of these diseases which averaged from 75 to 85 admissions per 1,000 during the canteen period would be more correct if multiplied by three. This would give us an admission rate during that period of from 225 to 255 per 1,000, against 163, the present rate. During the canteen period, in 1890, the rate at Columbus Barracks, Ohio, was 462 per 1,000, and at many of the other posts during that year ran as high as 250 per 1,000.

In discussing the prevalence of venereal diseases in the Army, advocates of the canteen fail to mention the fact that a large proportion of such diseases are brought into the army as recruits. Major Deane C. Howard, Medical Corps, surgeon at Jefferson Barracks, Missouri, states that 50 per cent. of the venereal cases treated at that depot were from infections contracted prior to enlistment. Jefferson Barracks is one of the principal recruiting depots of the army, through which many thousands of recruits pass annually.

Besides, hundreds of cases of syphilis, which are carried on the sick reports today were contracted prior to enlistment or are of long standing, and were brought to light only through the Wassermann test on the blood. The Wassermann test, a recent medical discovery, was not known during the canteen period, and, in connection with the salvarsan treatment, has caused thousands of unfortunate young men, both in the army and civil life, who considered their conditions hopeless and never would have sought relief a few years ago, to seek medical examination and aid.

Under modern sanitation and prophylaxis, diseases of vice are rapidly disappearing and at many of our posts they have been reduced to a negligible quantity. The army is composed of young and virile men, who by nature are endowed with the passions of youth, which inspire many of them to seek society which cannot be found within the confines of an army post. That they become drunk and contract diseases of vice under our present regulations is not substantiated by the experience of our post medical officers.

Only recently the surgeon at Governors Island informed me that but two soldiers had contracted diseases of this character, among the command of nearly 400, since June last, who had taken prophylactic treatment, and attributed this remarkable condition to the fact that the men returned to their posts for disinfection. How many of them would have returned to the hospital had they been under the influence of liquor as the advocates of the army canteen contend?

During the month of November, 1912, in the Eastern Division, the constant rate of non-efficiency from diseases of vice amounts to three and a third men in each thousand, and the rate for December was even less,—two and one-fourth. This does not look as if "The American army is in a very deplorable condition physically," as published in the dailies, nor does it appear that two or three men in a thousand affected with vice diseases is as serious as a certain medical officer of the army has publicly reported. I do not believe that there is an

army in the world that can show a lower rate of non-efficiency from diseases of vice or alcoholism than the magnificent army composing the Eastern Division, under the command of Major General Thomas H. Barry, with headquarters at Governors Island.

The establishment of saloons in the vicinity of army posts has existed from time immemorial. It is true that these saloons have been of a more primitive order than the so-called first class bars in our great cities. The indictment that generally they are low dives and brothels is not true, because many of them are owned and run by discharged soldiers whose wives and children live in the same buildings.

During my service at Fort San Houston, Texas, 1893 to 1897, every street which surrounded the post contained saloons. This was also the case at Fort Hamilton, Brooklyn; Fort Wingate, New Mexico, and practically at all of the posts near which available saloon cites could be secured. In spite of the well equipped canteen at Fort Wingate, New Mexico, low drinking dives on the border of the reservation six miles away enticed the men at pay day, where they were not only drugged and robbed, but occasionally murdered, and this condition was well known to the War Department at the time.

The sale of beer in army posts has little or nothing to do with the suppression of outside saloons. On the other hand, the canteen becomes the kindergarten for the young recruit and the training school for the alcoholic habit. A few drinks in the canteen, a few more in the nearby saloon and the young soldier migrates to the red light district.

I have served nearly forty years in the army as a medical officer, twenty-three of which were spent at army posts in the direct care of the men. During the past fourteen years I have served as Chief Surgeon of army corps, divisions, and departments. As the senior medical officer in length of service in the army, I yield to no one in superior knowledge of the sociological condition of the enlisted men and certainly not to magazine writers, newspaper correspondents, and others who feed an eager public on misleading and degrading stories of the American soldier. Our army contains thousands of self-respecting young men, who resent the condemnation that they are unjustly receiving through the press.

The question arises whether drinking can be indulged in to the extent of securing the pleasurable sensations without harm. If so, what is the safety limit? Everyone differs in degree of immunity against infection and disease and so it is with alcohol, where we find some men killed by doses apparently harmless to others. The daily influence of beer and light wines has its permanent effect on the young soldier's health and physical condition, just the same as the persistent individual drop of water, which erodes and wears away the granite rock.

Let us examine into the psychological and pathological effects of beer and see whether it is a harmless beverage. From careful post-mortem examinations of hundreds of its victims it has been found that the constant use of beer produces the same character of mental and physical degeneracy, which follows other forms of alcoholic beverages. In beer drinking countries and especially among brewery employees, we find the flabby, fatty, and enlarged heart, which, in Europe, is known as the beer drinker's heart.

Dr. Bergen, a prominent insurance examiner, says that beer kills quicker than any other form of alcoholic beverage, basing his statements on insurance examinations. Through its degenerating effects on the blood it predisposes its habitués to the same risks from pneumonia, pleurisy, erysipelas, and other infectious diseases, as whiskey and brandy. He also claims that beer inebriates are less curable than those who develop delirium tremens from whiskey, and that while the beer drinker is often the picture of health, he is more subject to diseases and criminal tendencies than the whiskey drinker.

Dr. Clement Dukes, physician to Rugby, states that "Beer is a drug which deadens will power and excites the animal instincts of the young. Its relations, therefore, to immorality are most momentous." I have frequently interrogated our young soldiers on this point and have invariably been told that beer is more productive of erotic desires than whiskey or other alcoholic drinks.

The steady beer drinker is never in a normal condition, and, besides, he is more or less unfit for his higher duties. This is expressed in the rifleman by an unsteady hand and a poor score. The best results at target practice are secured from men who do not drink, especially during target season nor a considerable period before it begins, in order to steady the nerves. A peculiarity of the drinking man is that he deceives himself in believing that he is able to do as good work as the abstainer.

During my five years in the Philippines, I found the effects of malt drink on men worse than whiskey. In many cases it proved such an irritant to digestion, and especially to the liver, that many of them had to give it up. It was for this reason that both the officers and men preferred Scotch highballs, which proved less irritating and more acceptable to the stomach. The health of more men was injured during the Philippine insurrection by beer than through the infected drinking water which was the cause of amebic dysentery.

I have watched the effects of alcohol on the mental and physical condition of our officers and men for more than a generation and have never seen one that it has benefited. On the other hand, I have observed its injurious influences on thousands of our soldiers, and have known hundreds of officers who were cut down in the prime of life, dismissed or rendered useless and retired on account of drinking. The army of today is abstemious as compared with the drinking army of the canteen days, and anyone who states the contrary is ignorant of its previous history.

The use of any mild form of alcoholic drink leads to the habits of strong drink. Besides, the social environment of the beer club would eventually force the young abstaining recruit to drink. Very few of these men would be able to withstand the influences of the drinking non-commissioned officers and older soldiers. Those who drink use the argument that drinking at the canteen adds to the dividends of the club. With a bar, the post exchange becomes a loafing and drinking place and many of the young soldiers would be forced to drink to escape the taunts and jeers of the drinking element.

In considering the final results, there is little to choose from between beer drinking Germany, wine drinking France, ale drinking England, whiskey drinking Scotland and Ireland, or mixed drinking America. It is the poisonous agent, alcohol, which is concealed in varying degrees, and not the other

constituents of the beverage. The underlying arguments of the saloon men is that by governmental sanction of the canteen the government places its stamp of approval upon drinking, which would prove of inestimable value to the liquor interests and correspondingly damaging to the temperance movement.

In view of our knowledge of the effects of drinking, has the government the right to prohibit the use of alcohol among its public servants, especially among the pensionable class? Admitting that it is the private affair of the ordinary individual who elects to drink, does it not become a governmental affair when a pensionable official not only injures his health thereby, but reduces his efficiency and usefulness? We are living in a progressive and sane age and there is no place in this busy world for the tippler or barroom habitué.

No discussion of the army canteen would be complete without reference to the Post Exchange. Following the abolishment of the army beer saloon in 1901, Congress made liberal provisions for the creation of elaborate exchange halls at many posts in the army, in addition to the splendid Y. M. C. A. buildings erected and equipped by Miss Helen M. Gould, who is known throughout the army and navy as the soldier's and sailor's best friend.

Many of the post exchange buildings have cost as much as $40,000 and are splendidly arranged for the entertainment and comfort of the men. They are provided with well equipped gymnasiums, bowling alleys, billiard and pool rooms, amusement rooms for cards and other games, libraries, kitchens and cafés, besides the sale room in which the soldier can secure all those little articles necessary for his personal use not provided by the government.

There is no good reason why the post exchange should not become the most successful soldier's club in the world. Congress has been generous in providing the necessary funds for the buildings and equipment and the War Department has issued the necessary orders for its regulation and management.

The post exchange, without the beer feature, is a failure today because the government does not get the proper cooperation from its management. Too much attention is paid to creating dividend for the company funds and too little to the pleasure and amusement of the men. In discussing the question of the canteen with an old retired officer several months ago, he told me that his company had received a $400 dividend in three months at a two-company post, after its establishment, and for this reason he regarded it as a good thing.

Such dividends might almost be regarded as hold-up or blood money, because a large portion of them accrued from the sale of canteen checks, which were guaranteed by company commanders and taken from the men at the monthly pay table. These orders were issued after the men had spent all of their cash and were turned in for beer which would not have been drunk except for the checks. Should the canteen ever be restored, may the Lord deliver the men from the pernicious advance or check system!

The enlisted men of to-day are young, the majority of whom average from twenty to twenty-five years. Like other young men in the world of corresponding age, they are filled with the desires and passions of young manhood, which could not be suppressed were the War Department to establish a line of free beer saloons for the use of the men from Maine to Manila.

If the War Department really desires to improve the condition of the soldier, let it place a premium on temperance through official recognition of the abstaining class. Men are paid for superiority in marksmanship, and why not pay for total abstinence, which is the greatest factor of them all in promoting the efficiency of the army and raising its standards?

Those who cherish the hope that alcoholism and diseases of vice will vanish some day from the army, should never expect this ideal condition among beer-drinking soldiers.

## PARALYSIS OF THE RECURRENT NERVE DUE TO CIRCULATORY LESIONS;*

### WITH REMARKS ON RECENT THERAPEUTIC MEASURES.

By J. W. GLEITSMANN, M.D.,

NEW YORK.

Although I am not in a position to offer any new observations of my own I thought a short résumé of the subject may be of interest to you, as the data are widely scattered in the literature, and as a few therapeutic measures have of late been recommended, which seem to hold out a prospect of relieving an otherwise unamenable condition.

To facilitate the disposal of the subject, I have divided the paper into five parts: (1) Brief physiological remarks; (2) Recurrent paralysis from heart lesions in general; (3) Paralysis in connection with mitral stenosis; (4) Aneurysm; (5) Therapeutics. In no instance has it been my aim to give a complete literature, and I shall only quote publications referred to in the text.

I. *Physiological Remarks.*—Although abductor paralysis does not come within the scope of this paper, it is necessary to allude to it briefly in order to appreciate certain features of recurrent paralysis. You are all familiar with the proclivity of the abductor muscles to paralysis, and the reason for it is explained by Grabower,[1] who by painstaking observations counted the number of terminal nerve fibers of the laryngeal muscles. He found that of all the laryngeal muscles the posticus has the smallest number of nerve terminals, absolutely as well as relatively in regard to its size; a view he still adheres to according to a letter written to the speaker in March of this year, while others, *e.g.* Semon, believes more in the great vulnerability and the biological differences in the muscular structure of the abductors.

We also know that a recurrent paralysis can change to an abductor paralysis, because the stronger adductor muscles recuperate quicker than the abductors, if the underlying lesion shows a tendency to improvement. Louis Elsberg[2] reported already—1882—the case of a young boy who, after a violent exertion, became aphonic on account of the cadaveric position of the cords which, during convalescence, moved gradually to the median line, followed by dyspnoea of such a degree as to necessitate tracheotomy. In Semon's[3] patient a recurrent paralysis with almost complete loss of voice terminated in an abductor paralysis, enabling the patient to resume his vocation as a professional singer. The speaker[4] treated a patient with an old syphilis, a left recurrent paralysis, an aneurysm

*Read before the Section of Laryngology of the New York Academy of Medicine, November 27, 1912.

of the aorta, and a stenosis of the left bronchus from infiltrated mediastinal glands. The latter yielded to antiluetic treatment, and the pressure on the abductor fibers being relieved, the cord assumed the position in the median line, with return of the singing voice. A most remarkable observation is related by Landgraf,[5] whose patient acquired in the course of articular rheumatism a left sided pleuritis and a pericarditis, causing paralysis of the left abductor, which after two weeks changed to recurrent paralysis. The latter began to improve with absorption of the pericardial exudate, and after several months the motion of the left cord was almost fully reestablished.

Finally, the observation that the glottis is wider in the dead than in bilateral recurrent paralysis is of greatest importance to explain some phenomena, about which decided differences existed and probably still exist. The greater width of the glottis in the dead is due to the inaction of all the laryngeal muscles, while in recurrent paralysis the external tensor, the cricothyroid muscle, which is innervated by the superior laryngeal nerve, still retains its function, which results in an approximation of the cords.

The position of the vocal cords near the median line after an experimental surgical severance of the nerve made Grossmann[6] contest, that the glottis stood in the cadaveric position in such cases and that therefore the assertion that posticus paralysis alone caused the position of the cords in the median line was erroneous. Experiments made by Grabower[7] on dogs showed soon the fallacy of Grossmann's contention. He found it to be true that after severance of the recurrent a position of the cords near the median line resulted within ten to thirty minutes, but that the cords receded from this position after one to four days and assumed the cadaveric position, in which they remained. This change of the position of the cords is due to the inability of the thyrocricoid muscle to retain its function of extension and thereby adduction of the cords any length of time, if unaided in its action by the adductors, when they are paralyzed.

II. *Recurrent Paralysis from Heart Lesions in General.*—Gantz[8] gives the history of a man whose heart was enlarged in every direction and who had stenosis and insufficiency of the mitral valve and paralysis of the left recurrent. The diagnosis of the paralysis being caused by the mitral stenosis was not verified by the autopsy, which showed an enormous hypertrophy of the peribronchial and peritracheal glands exerting direct pressure upon the nerve. Low[9] presented to the laryngological section of the Royal Society—1906—a young woman who had a history of severe rheumatic fever with subsequent pericarditis. Her left recurrent paralysis was in his opinion due to adhesions fixing and dragging on the nerve. Several cases of recurrent paralysis in consequence of pericarditis are found in the literature. Pericardial effusion was also the cause of bilateral recurrent paralysis, which disappeared with absorption of the exudate. This observation by Bauemler[10] is, as far as I know, the only instance of a cure of bilateral recurrent paralysis due to organic disease.

Syphilis of the aorta—mesoaortitis—combined with infiltrated bronchial glands is considered by Fein[11] to have been the cause of a left recurrent paralysis, as all the symptoms disappeared after specific treatment.

III. *Recurrent Paralysis and Mitral Stenosis.*—Ortner[12] published—1897—the first observation of left recurrent paralysis due to mitral stenosis. He attributed the paralysis to compression of the nerve between the aorta and the distended auricle, which was confirmed by the autopsy. But by subsequent observations it was found that the pathological lesions producing recurrent paralysis in mitral stenosis showed a great variety of local conditions, and were in many instances of a different character than in Ortner's case. Four years later Kraus[13] related the history of a patient with mitral stenosis, tricuspid insufficiency, and hypertrophy of the right ventricle in whom the Roentgen rays showed enlargement and displacement of the heart. The autopsy proved that, in consequence of the latter, the relationship of the aorta and pulmonalis had changed, and that traction was exerted on the nerve by Botalli's ligament.

I shall not weary you with histories of patients who presented different local conditions in mitral stenosis found at the autopsy. Fetterolf and Morris[14] have briefly analyzed in a recent paper the results of autopsies of the eleven cases found in the literature. They stated that recurrent paralysis was attributed to direct compression on the part of the auricle or its appendix in seven cases, to cardiac displacement in one, to the effect of persistently patulous ductus arteriosus in one, and to indirect compression acting on the pulmonary artery in two cases. In addition, 26 clinical cases without autopsy are reported in the literature. An excellent résumé of the subject, wth appended literature, is also published by Garel.[15]

IV. *Recurrence Paralysis Due to Aneurysm.*—The deleterious influence of aneurysm of the aorta upon the recurrent nerve was already recognized in the pre-laryngoscopic time. Legroux,[16] in an address to the Academy of Medicine of Paris—1853—spoke of the weakness of the voice, partial aphonia, hoarseness, which he attributed to the compression of the recurrent by an aneurysm. He referred to a case reported by Banks[17]—1851—in which the autopsy showed an enormous dilatation of the aorta pressing against the œsophagus and the upper part of the left lung. The pneumogastric nerve was flattened by pressure and all the muscles were completely atrophied on the left side of the larynx.

The first laryngoscopic observation was made by Traube[18] in a patient who was hoarse and coughed since three months. The left cord did not move at phonation, and the diagnosis was aneurysm of the aorta and paralysis of the left recurrent. One year later he reported a second case of the same nature.

When we find a left recurrent paralysis and an aneurysm of the arch of the aorta, there is very little doubt as to its causation. But we all are well aware how difficult it is sometimes to determine the true lesion, in spite of a most careful examination. It is not the place here to mention the different affections, but I may be permitted to refer to one condition, viz., rheumatism, of which the first case was reported by Kidd.[19] A bilateral recurrent paralysis developed in the course of an acute laryngitis, with subsequent complete recovery. Another case of the same nature is described by Semon,[20] in whose patient the bilateral recurrent paralysis changed gradually to bilateral abductor paralysis, necessitating tracheotomy.

Although a number of recurrent paralysis of rheumatic character are recorded, we have to be very careful to attribute the paralysis to rheu-

matism, as by a longer observation of the patient and by the use of modern therapeutic means we may be able to find a true pathological lesion. Levinstein[21] treated for some time a patient with right recurrent paralysis, which he had good reason to believe of rheumatic origin. Finally he used Roentgen rays and found an aneurysm of the right subclavia, with compression of the right recurrent.

Finder[22] relates the history of a patient with recurrent paralysis, aortic aneurysm and locomotor ataxia. He found in one clinic the report of 24 autopsies of cases of locomotor ataxia, nine of which, viz., over one-third, had also an aortic aneurysm. He therefore advises strongly to examine tabetic patients with recurrent paralysis to make sure that no aneurysm is present before we attribute the paralysis to locomotor ataxia.

Bilateral recurrent paralysis, due to aortic aneurysm, is a rare occurrence, and is caused by a very large aneurysm, or such, involving the trunk of the anonyma and the subclavia. Bernhard[23] gave a short analysis of all the 19 cases found in the literature up to 1903. Although pressure on one recurrent nerve can affect the laryngeal muscles on the one side only, we must not lose sight of the fact that according to Johnson,[24] pressure on one pneumogastric can through the afferent fibers of the latter transfer an irritation to the accessory fibres and produce a paralysis of the other side. Another explanation is that continuous irritation of one pneumogastric creates structural changes in its centers and thereby affection of both accessory nerves.

V. *Therapy.*—As stated in my introductory remarks, I shall confine myself to recent therapeutic measures, which their authors have found to give relief in recurrent paralysis.

Horsley[25] saw a patient—1909—whose left recurrent was injured by a bullet, and who three months later showed complete paralysis. By an incision along the sternocleidomastoid he excised part of the diseased ends of the nerve and brought them together with chromic catgut, drawing muscular tissue over the suture. Improvement began after two months, and after nine months the nerve had fully recovered.

Navratil[26] experimented on four dogs and made an anastomosis of the recurrent nerve with the descending branch of the hypoglossus. He guarded the sutured nerve ends according to the method of Foramitti,[27] by covering them with a tube made from fresh animal vessels. The autopsy of a dog which died after some time showed already a union of the nerve ends, and in some places presence of neurofibrillar formations.

Grabower[28] published a highly interesting case, which confirmed his statement as to the function of the cricothyroid muscle, mentioned previously. A woman was operated upon three times for goiter, which had exerted pressure upon both recurrent nerves. Without going into the details of the case, the adductors of both sides recuperated, drawing the cords toward the median line with resulting dyspnea, necessitating tracheotomy. As Grabower believed that the action of the adductors was greatly influenced and supported by the intact cricothyroid muscle, he advised neurectomy of the superior laryngeal nerve of one side. This assumption proved to be correct; the left cord began to recede slowly from the median line, and six weeks later the tracheal cannula could be removed.

The same gratifying result from neurectomy of the superior laryngeal nerve in a similar case is reported by Mertens,[29] in whose case the tracheal cannula could also be dispensed with.

The latest and last procedure to lessen the distressing features of unilateral recurrent paralysis was communicated to the Society of German Laryngologists by Bruenings,[30] who one year later reported to the same society the condition of the patients he had treated. His endeavor was to relieve the unpleasant symptoms of respiration, viz., the unsatisfactory expectoration, the inability to use pressure, as well as those of phonation, weakness of voice, waste of air. In order to counteract the atrophy and weakness of the paralyzed cord and to restore its previous phonatory position, he made injections of paraffin into the cord. As a rule he succeeded with two applications, using in the first one three injections, viz., anteriorly, posteriorly and in the middle; and in the second one, after 5 to 8 days, filling out the interstices. The laryngoscope showed after a short time that the cord presented a straight line and was in a phonatory position. Two of these patients regained their voice, the third one, with an old bronchitis, felt great relief by being able to expectorate.

One year later he related five more cases with similar results. He had in no instance ill sequelae, and his oldest patient spoke—1912—with an almost normal voice.

# THE CARE OF SPEECH DEFECTIVES.

By E. W. SCRIPTURE, Ph.D., M.D.,

NEW YORK.

ASSOCIATE IN PSYCHIATRY, COLUMBIA UNIVERSITY.

Speech defects include a number of different troubles, among which the chief ones are the following:

(*a*) Stuttering. This is a disease whose symptoms include cramps and contractions of all the muscles involved in speech, but whose essential pathological fact is a special state of mind.

(*b*) Pseudo-stuttering. This is a symptom that occurs in many diseases, including tic-speech, hysteria, cerebral spasticity, athetotic conditions, aphasia, some forms of amyotrophic lateral sclerosis, etc.

(*c*) Negligent Lisping. This includes a large number of defects due to defective perception and execution of sounds. The trouble appears not only in normal children, but also in cases of backward development, defective mentality, etc.

(*d*) Organic Lisping. This includes all the defects of speech that arise from defects of the tongue, teeth, palate, velum, ears, etc.

(*e*) Neurotic Lisping. This is a peculiar but fairly frequent disease that resembles ordinary lisping in its external symptoms but is closely allied to stuttering in its real nature.

(*f*) Cluttering. This is a disease also resembling lisping in its symptoms, but derived purely from nervousness.

(*g*) Athetotic Speech and Spastic Speech. These are two forms that occur not very rarely among children.

(*h*) Several other forms of speech defect are much less frequent, but they must not be confounded with any of the preceding.

Although in many cases it is easy to detect a stutterer, in many other cases serious mistakes have been made; not only has a stutterer been classed as something different but those who are not stutterers have been put into this group. Other forms of speech defects are often very difficult to diagnose correctly. No one can do this with the requisite degree of certainty unless he has been properly trained.

The treatment of stuttering is a most difficult affair, requiring a high degree of skill. In my experience in this specialty, I have met many cases that have been cured with the greatest ease by simple methods, but also very many who have taxed my skill and patience and endurance to the utmost. Some stutterers will get well without treatment, some can be cured by Christian Science, but the majority can never be cured by any simple or routine procedure or by any one except a skillful expert.

The treatment of stuttering by routine methods has always led to the ultimate failure of anyone who has attempted it. The innumerable physicians and stutter-curers who have tried to treat patients by such methods have all eliminated themselves in the course of time.

It would be a movement not only detrimental to the public interests but also fatal to the reputation of this work to permit any teachers to engage in it who have not had the proper training under an expert.

It is necessary to insist upon two things: first, that all teachers of classes for speech defectives shall be trained under a supervision sufficient to keep them from making many mistakes; and second, that the classes for speech defectives shall be inspected at fairly frequent intervals by medical experts.

We must consider several arguments that have been advanced in discussing this matter.

*First.* Speech defects include only two groups, namely, stuttering (often called stammering), and defective enunciation.

My experience shows that only about seventy per cent. of speech defectives belong to these two groups.

*Second.* Anybody can tell whether a child is a stutterer or not.

My experience shows that even with many years of specialization in this subject, I still occasionally make mistakes and classify as a stutterer one who has an utterly different trouble. On the other hand, many a stutterer is able to so conceal his trouble that it is not apparent to his teacher or else it is assumed that he is a mental defective.

*Third.* It is easy to give a correct diagnosis in regard to defective enunciation.

The contrary is true. Defects in enunciation may arise from the most varied causes. The most frequent one is negligent attention in an otherwise normal child. Almost as frequent is a condition of mental defectiveness. Very frequently there is some defect of the speech organs. There are numerous other cases which are directly traceable to nervous and mental diseases. An absolutely certain diagnosis is often an affair of very great difficulty for the expert.

*Fourth.* The treatment of speech defects consists in some simple exercises.

Such a supposition is fatal to the success of the work. Each form of defective enunciation requires a different method of treatment. As stated above, stuttering shows itself in so many different forms, and requires so many different methods of treatment that a command of them all taxes even the expert.

*Fifth.* Examination and diagnosis by a medical expert are unnecessary.

Such an error hardly requires comment. Proper examination of the speech organs can not be made except by a physician thoroughly familiar with the anatomy of the nose, throat and larynx; a complete understanding of stuttering cannot be obtained except by a neurologist. The case is analogous to that of optometry. Glasses may be correctly fitted to certain eyes by an amateur but only the physician is capable of a reliable diagnosis that will protect the patient from injury.

The medical profession should firmly insist that every child selected for treatment in a speech class shall be sent for diagnosis to a competent physician. With convenient speech clinics this will involve no expense to the school or the parent. The proper training of the special teachers for the speech classes is a matter for the consideration of the Board of Education.

The medical profession should provide proper clinics where the speech defectives can be examined. There are at present only three or four speech clinics in this entire country. There are only two places where undergraduate instruction is given on this subject. In spite of a steady demand for it there is no place at all where post-graduate instruction is provided.

# LARGE DOSES OF ANTITOXIN GIVEN EARLY—A MEANS OF PREVENTING LARYNGEAL STENOSIS.

By LOUIS FISCHER, M.D.,

NEW YORK.

ATTENDING PHYSICIAN, WILLARD PARKER HOSPITAL.

Diphtheria is by no means extinct. It will always recur in congested districts where infection can be spread. It is spread by convalescent children or by patients exposed to the disease, whose throat harbors live diphtheria bacilli—diphtheria carriers. It is essentially a child's disease, although adults contract it frequently. If the disease continues unrecognized the toxin absorbed causes an overwhelming state of poisoning, which in turn affects the heart, lungs or kidneys. Such neglected cases must be considered septic types, in which the local process in the throat is of secondary importance, and unless the general toxemia is taken into account when treatment is instituted such cases end fatally. The following cases are interesting because they occurred in this city, all of them seen in consultation, and all terminated favorably.

Case I.—Baby Herman, 21 months old, was seen by me in consultation with Dr. M. Altman on December 23, 1911. He was suffering with patches on the tonsil and pharynx, and a slight croupy cough. The infant received 5,000 units of antitoxin in the morning and six hours later an additional injection of 3,000 units. The temperature was 103.4° F. In addition to the antitoxin I ordered a saline laxative to be given hourly until liquid stools were produced. Antitoxin (10,000 units) was injected morning and evening until the temperature came down to normal. In all 45,000 units were needed to bring the temperature down to normal. The croupous cough and mild laryngeal stenosis which were present at the first consultation gradually lessened and the child made a complete recovery. Total time from the first visit until the case was discharged cured was ten days.

Case II.—Baby Sanford, aged 16 months, was seen by me in consultation with Dr. G. Hamburger, who reported the following: The tonsils and pharynx are covered with a whitish membrane; pulse rapid; temperature 103°. There is laryngeal stenosis; infant is irritable and restless. The stenosis increased and the infant was injected with 10,000 units of antitoxin. The following morning the infant was weaker, more nervous, and restless. An injection of 20,000 units was given. Prostration and restlessness increased; there was a distinct diminution in the quantity of the urine; the pulse became weak and irregular. The examination of the chest showed many râles, evidences of diffuse capillary bronchitis. When I first saw this case the membrane had begun to exfoliate. The stenosis improved rapidly and mucorrhea continued. Owing to the profound toxemia the heart sounds were irregular and the pulse required constant stimulation to bring it up to normal. Although the urine was scant, neither albumin nor casts were found. The child made a complete recovery in about four weeks.

Case III.—Baby E., three and one-half years old, was seen in consultation with Dr. S. Buchenholz. When first seen by the Doctor the infant had been ill with wheezing and cough about one day. Patches of diphtheria being visible, the diagnosis of diphtheritic laryngitis was made and 5,000 units of antitoxin were injected. The temperature at this time was 102° F. After the injection the temperature rose to 103°. Seven hours after the first injection another of 20,000 units was given, and the following morning and evening the dose of 5,000 units was repeated. As the stenosis increased and there was severe retraction of the chest I was requested to see the child in consultation, and decided to intubate at once. I introduced a No. 3 tube without using force, and the laryngeal stenosis was immediately relieved. The tube was worn about five days in all, and as the laryngeal stenosis subsided I waited until the temperature became normal, and then extubated, as previously stated, on the fifth day. One intubation and one extubation were performed. The only complication was hoarseness, probably due to pressure on the vocal cords. The voice gradually returned to its normal condition. No permanent complication followed, and the child was discharged in an excellent condition.

Case IV.—Male, 4 years old; first seen on October 2, 1912, in consultation with Dr. Littenberg. Had a cold for the previous two weeks. On October 2 increasing hoarseness and difficulty in respiration had been complained of all day; when seen at evening about 7 P. M. the throat was negative, but at 10 P. M. a very small white patch was present on the right tonsil. Temperature 101°, pulse 120, respiration 38. Diagnosis was made of pharyngeal and tonsillor diphtheria, and 8,000 units was injected that evening. On October 3 large patches were found on both tonsils, dyspnea was very much less; temperature 104°, pulse 140 and not very strong, respirations 28. Five thousand units more was injected, and in the evening the dyspnea ceased; temperature 103°, pulse 150 and very weak, respirations 20. Then antitoxin to the amount of 13,000 units was injected in two doses, morning and evening. Throat cleared up slowly; patches were quite small. Oct. 4 dyspnea ceased; temperature 100°; pulse 140, irregular but stronger than previous day; respiration 20; throat entirely clear; voice also quite clear. Oct. 5, respiration and temperature normal; pulse 100, irregular and intermittent. Distinct evidence of myocarditis and nephritis were present. Oct. 13, edema of the scrotum and also of the eyelids were present. Urine contained a trace of albumin, many hyaline and a few granular casts. The temperature that evening was 100°. Oct. 14, scrotal edema had disappeared, but edema of the eyelids was still present; temperature normal. On Oct. 15-18 edema of the eyelids had disappeared and the temperature was normal. The urine contained a faint trace of albumin and a few hyaline casts, but many fields had to be searched before any were found. The pulse was found to be irregular, intermittent and varying in frequency from 60 to 110. On Oct. 24 the pulse was improved, rate about 90, and patient had fully recovered.

From a study of these four cases it is evident that effectual treatment consists in giving a large injection of antitoxin at the beginning of the treatment. In a severe case 10,000 to 20,000 units should be injected at the beginning; whether or no more antitoxin should be injected must depend on the result of the first injection. In all of the cases reported the first injection seemed insufficient, and it does seem that the additional doses help to modify the toxemia. Park maintains that one injection given at the beginning, be it 5,000 or 10,000, is sufficient; he maintains that antitoxin can be found in the blood many days after such injection, and

since antitoxin can be found in the blood he insists that no more should be injected.

My rule in intubation and extubation has been: (1) Avoid force; thereby avoid injury. This rule has been my greatest aid in preventing retained tubes. (2) Do not hurry. While in a severe laryngeal stenosis a given amount of haste is necessary in selecting the proper sized tube and making preparations, but when it comes to the introduction of the tube the inflammatory process and subnormal condition must be remembered; hence, one should go slow. The nervous and frightened child must be quieted, especially when considering extubation. My rule is to give an antispasmodic for twelve hours preceding the removal of the tube. Codeine, one-eighth to one-fourth of a grain, to a child two years old or over, repeated in three hours for four doses, or ten-grain doses of sodium bromide with two grains of chloral hydrate, repeated in six hours (two doses only), will allay nervous excitability and have a quieting effect. The antispasmodic should be continued for twenty-four hours after the removal of the tube. The spasm due to fear of the operating table when repeated intubation and extubation are practiced may in rare cases require an inhalation of a few drops of ethyl chloride prior to extubation. Dover's powder is a valuable drug as an antispasmodic prior to extubation. Intralaryngeal medication consists in applying a coating of medicated gelatin to each tube. Such medication as orthoform, 10 per cent. in gelatin or ichthyol gelatin, served me well in a case of persistent tube, reported seven years ago. Owing to the thickness of the coating of gelatin a tube one size smaller than usual is required.

*Subcutaneous Method.*—In severe cases of diphtheria it is better to give 10,000 units by hypodermic means. As a rule some benefit should be noted within twelve hours after such treatment.

*Intravenous Method.*—If septic manifestations are evident, especially if the case has been untreated for many days, the most rapid method of destroying the diphtheritic poison is by injecting into the median basilic vein at least 10,000 to 20,000 units.

162 West Eighty-seventh Street.

## THE ETIOLOGY OF IRITIS.

By GEORGE W. VANDEGRIFT, A.M., M.D.,

NEW YORK.

INSTRUCTOR IN OPHTHALMOLOGY CORNELL MEDICAL COLLEGE, ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY, VISITING OPHTHALMOLOGIST WILLIAMSBURG HOSPITAL, BROOKLYN.

The recent advances in clinical pathology of the various internal infections make our usual classification of the causes of iritis incomplete and unsatisfactory. It is the habit of the human mind to explain an effect by the cause nearest at hand. We have believed always, and not without apparent reason, that rheumatism bore some etiological relationship to iritis; therefore, when in the presence of iritis we found a history of rheumatism no matter how remote or indefinite we called the case rheumatic iritis. More than propinquity or family resemblance is necessary to-day to establish relationship. Serum reactions and other laboratory findings as well as therapeutic tests are called for to prove cause and effect.

The old classification of iritis recognized three etiological types, (1) idiopathic, (2) symptomatic, (3) traumatic. The first long ago should have been dismissed. It includes that group into which we place all cases of which either from ignorance or lack of thorough study the cause is unknown. These cases all fall within the last two groups and their number diminishes as our knowledge increases of the relation of the eye to other parts of the body. The iris is part of the circulatory tunic of the eyeball and is in direct connection with the circulation of all other organs. An infection in the general blood stream pervades the iris and reaction takes place which may or may not be perceivable.

We are very prone to consider the organ in which we have special interest as being a thing apart. If we continuously bear in mind that the iris, particularly its circulatory coat, is an integral part of the body we will discover that the diseases arising in its own structure are few and far between; and the type of disease we call iritis probably does not arise primarily in the iris tissue but is symptomatic to some infection derived from without or from within the body through the blood stream. Therefore, we can classify all cases of iritis as exogenous, deriving its infection through a wound connecting with the outer surface of the body, and endogenous deriving its infection from within.

A further classification is made usually into primary, in which the iris alone is involved, and secondary, in which the iritis is the result of extension of inflammation from other portions of the eyeball. It is improbable, however, that the iris can be inflamed without involvement of the other portions of the uveal tract, Descemet's membrane, ciliary body, and choroid; and vice versa these cannot be diseased without some involvement of the iris, be it ever so slight. But the diseases of Descemet's membrane, ciliary body, and chorioid can be divided also into exogenous and endogenous; and a little thought, therefore, will show that the terms primary and secondary are unwarranted, even if convenient.

We are in position now to consider more in detail the factors concerned in the causation of these types, exogenous and endogenous. Of the former there is little difficulty of diagnostication, for the condition is the result of traumatism either accidental or operative, and the common varieties of pyogenic organisms or their toxins are present. In the latter or endogenous group are included the many internal diseases usually assigned as the cause of iritis. Here our interest mostly centers, for we find not only the ordinary cases of iritis, but also those cases of uncertain or unknown origin, which have been classified as idiopathic. It will be profitable, therefore, to study a little in detail some of these etiological factors.

*Syphilis.*—While statistics differ (varying from 10 to 75 per cent.), it is generally conceded that syphilis, inherited and acquired, is the chief cause of iritis. With inherited syphilis the iritis is of the ordinary type presenting nothing pathognomonic of lues, unless it be accompanied by a gumma in the iris tissue. The inflammation may occur alone or with interstitial keratitis. In acquired syphilis the iritis takes one of two general types, either a simple inflammation presenting macroscopically and microscopically nothing distinctive, or a type which is always pathognomonic of syphilis. Of the latter type there are two forms, papillary and gummatous.

Papillary iritis is an ordinary plastic inflammation accompanied by nodules of various sizes confined to the pupillary zone. The nodules may be single or multiple. They appear during the second stage coincident with or soon after the rash, and they closely resemble the papillary syphilides.

Gummatous iritis is a tertiary affection and presents as a gumma, single and monocular usually, in the ciliary zone. It frequently has its origin in the ciliary body.

The presence of papillary or gummatous iritis makes positive the diagnosis of syphilis, but that of a simple plastic iritis even in conjunction with other symptoms is not necessarily significant of syphilis, for it may be due to a complicating infection. This is particularly true of iritis that develops several years after a primary infection.

Gonorrhea and Rheumatism.—For several years the attention of ophthalmologists has been directed to gonorrhea as a cause of iritis. As many cases of articular and non-articular rheumatism are of gonorrheal origin, so also the attacks of iritis that frequently follow them have been found to be due to the same cause. True articular non-gonorrheal rheumatism is rarely complicated by iritis, but rather that indefinite chronic rheumatism, non-articular in type, which undoubtedly is due frequently to toxins derived from a urethral gonorrhea or other local infection. Gonorrheal articular rheumatism is very prone to be accompanied by an attack of iritis, being a member of the syndrome urethritis, rheumatism, iritis.

While the majority of cases of iritis due to gonorrhea are preceded by joint involvement there is no doubt that the iris as well as other parts of the uveal tract can be affected without an antecedent articular rheumatism which has been proven by statistics of Nettleship, and by a case of chorioiditis reported by me in the *Journal American Medical Association* for June 8, 1912.

A few observers have attempted to describe a distinctive picture of gonorrheal iritis, but no more than a suggestion of certain tendencies can be made clearly. It is of the plastic variety, more liable than other forms to be accompanied by a metastatic conjunctivitis, and is apt to be violent and intractable to treatment; but so many cases, both severe and mild, go unrecognized as to their gonorrheal origin that as yet any attempt to depict a particular form is unsuccessful. A more general use of the complement fixation test will aid in clearing up these obscure phases of the subject.

Autointoxication.—There is no doubt that the absorption of toxins produced by intestinal putrefaction is of etiological significance in the causation of inflammation of the uveal tract including the iris. Cases of iritis negative to all tests and accompanied by urinary findings of intestinal putrefaction have been cured by the eradication of the toxemia combined with ordinary local treatment to the eye. This, of course, is not a positive therapeutic test, for many cases of iritis even of obscure origin subside under local treatment alone. But there are other cases, chronic in nature, that go along badly under various lines of treatment which begin to clear only when the intestinal putrefaction is found and stopped. There is no doubt also that such digestive disorder is a contributory factor in cases the direct cause of which may be another infection, such as diabetes. It is well to bear this in mind in the treatment of all cases of iritis of whatever origin.

Local Infection.—That localized purulent infections of various parts of the body will cause uveal inflammation is very probable. It has been shown that tonsillar affections, if purulent, will produce streptococcic poisoning that will simulate rheumatism. There is no reason why such an infection should not cause an attack of iritis. Other local infections such as septic uterus, alveolar abscess or sinusitis have produced cases of iritis observed by several writers. One case that I have seen was that of a woman who developed an iridochorioiditis during the course of a septic endometritis which did not begin to subside until after removal of the septic material from the uterus. A case more illustrative of intestinal toxemia was that of a young man treated by me for five different attacks of iritis between the years 1904 and 1907. No cause could be discovered until during the last attack the patient became aware that he was passing parts of a tapeworm. After being relieved of his unwelcome guest the attacks of iritis ceased and have not returned since.

The purpose of this paper is not to detail all the possible causes of iritis, among which may be found besides those mentioned above tuberculosis, diabetes, and acute infectious diseases such as influenza, typhoid fever, and malaria, but to suggest byways through which we may advance to a better comprehension of the etiology of iritis, a subject that offers much material for study and reflection.

## A PLEA FOR GREATER CONSIDERATION FOR THE OPIUM ADDICT.

By C. B. PEARSON, M.D.,

BALTIMORE, MD.

I DEFINE the opium habit as an imperative demand of the system for opium; followed by mental and nervous collapse, insomnia, loss of appetite, vomiting, cramps in the bowels, profuse perspiration, extreme restlessness, extreme prostration, and sometimes death when this demand remains too long unsatisfied. I mean by opium, opium in any form or any of its derivatives.

My excuse for writing this article is that there are still many physicians who can look upon patients presenting the above picture with indifference. And because there are still many who make light of the shock caused by sudden withdrawal.

Furthermore, my high percentage of permanent results in treating even very bad cases who have never before been treated, and my low percentage of permanent results in treating those who have relapsed after passing through the so-called "quick" methods of treatment, leads me to think that, aside from the immediate shock and suffering, there must in many cases at least have been permanent damage done to the central nervous system. I believe that the police or jail physician who refuses opium to addicts under short sentence or detention is not only doing no good whatever, because a short detention can produce no cure, but is doing something so brutally inhuman as to be out of touch with the civilization of the twentieth century. And, furthermore, he is placing a human life in danger, for they certainly do die sometimes; but, more than all this, I firmly believe that he is doing these poor wretches, who are already sufficiently unfortunate, permanent damage.

I have talked with many women who have given birth to children who have also endured the suffering of opium withdrawal, and all say with one accord that the suffering of childbirth is not to be compared with it. Any addict who finds himself in jail or police station would much sooner endure the suffering caused by starvation or thirst than be deprived of his opium. And yet if our prisoners

were deprived of food and water the whole country would at once be up in arms, and if they knew as well just what suffering the deprivation of opium meant to the imprisoned addict, they would be equally indignant.

Where prisoners are to be confined for long periods of time, a cure or death can be brought about by absolute withdrawal. It is just as easy to bring about the cure by humane methods as in any other way. As for myself, I could not endure the sight of the unnecessary suffering caused by absolute withdrawal, any more than I could stand by and see a leg amputated without anesthesia where there was no contraindications to its use.

Our judges, from the country justice to the judge upon the Supreme Bench, should know something of opium addiction in order that when they have any dealings with this unfortunate class they may be able to give intelligent expression to those humanitarian instincts which they usually possess. Our legislators also should know more about the matter. Their efforts in many cases, it seems to me, are crude and amateurish. In many cases the laws passed seem only to annoy and distress the unfortunate addict rather than to restrict the spread of opium addiction.

Remember that it has been found difficult to stamp out the use of alcohol by law, and alcohol is more bulky, it is harder to conceal in transportation, and its influence upon the individual is far more easy to detect.

A rigid enforcement of an unwise law would force the trade out of the hands of the legitimate druggists into the hands of a set of scamps who will not be restrained by conscience or anything else. And when that happens opium addiction will spread faster than it does now. Because such parties, being exposed to risk and danger, will naturally try to increase their business as a compensation for the risk.

The respectable druggist has no wish to increase his opium trade. Perhaps the most humane and at the same time restrictive law that could be passed would be registration of all addicts with the public health officials, and compelling the former to get an order from these officials whenever they wished to purchase a new supply. And physicians should be restricted to prescribing therapeutic quantities for strictly therapeutic purposes. But the actual addict should not be debarred from procuring his needed supply. It should be remembered, however, that no matter what laws are passed, as long as pain and suffering, insomnia, acute and chronic alcoholism are with us, opium addicts are bound to be manufactured.

And it also should be remembered that the causes just mentioned always have furnished, and probably always will furnish, the great majority of addicts. The number of recruits furnished by ignorant self prescribing, by nostrums containing opium, and by the opium smoking dens can, I believe, be lessened by law.

On account of the extreme sensitive and secretive nature of the opium addict, even as humane a law as the one I have suggested would, I believe, open a lucrative field for illicit dealers in opium. And these parties, as I have before mentioned, can be depended on to do all in their power to extend their trade. There seems to be a tendency in our law making bodies to attempt to remedy all sorts of evils by legal enactment. Whether they are right or wrong in this is too profound a question for my philosophy to solve.

I believe, however, that I am safe in saying that we should not lose sight of such old and tried means of civilization and uplift as home training, the school, the church, and the press. Our own profession should and I believe is exercising all due caution. Before we assume a carping attitude toward the profession let us remember the heart-rending pain and suffering that the profession come in daily contact with. As long as conditions are as they are errors of judgment are bound to ensue and opium addictions bound to result. Even though these occur but rarely, when we consider the vast extent of our country, the sum total must be a large army of opium addicts.

So far as our National Congress is concerned, if its members think that the import duty on opium has a tendency to restrict opium addiction they are mistaken. Opium is never expensive to the beginners. It is only after the poor wretch is firmly enmeshed in its clutches and after the ordinary therapeutic doses have been multiplied forty to three hundred times that the price begins to pinch. If revenue is the only consideration, let me humbly remind them that in many cases that revenue comes from poor women who have to earn their opium money, feeble as their health is, by taking in washing.

In all our public institutions, asylums, penitentiaries, almshouses, homes, etc., humane consideration should be given the opium addict. The very old and feeble should be given enough opium to keep them comfortable. The others should be treated by methods that are at once humane and rational.

I have only a few words to say about treatment. In the first place, no matter what has been advertised or what any one says, there is no such thing as a specific for opium addiction. Those who advocate the various quick methods do so perhaps to have the matter over quickly and save time. If we reckon time from the beginning of treatment until complete convalescence, by far the quickest method of treatment is intelligent reduction, so adjusted that the patient may be comfortable throughout the entire course of treatment. Then, again, many advocate the quick methods because they imagine that no improvement can take place until all the opium is out of the system. This is a mistake. I have had patients gain forty pounds by the time the last dose was withdrawn. Others advocate the quick methods because they imagine that so much suffering is necessary anyway.

If the problem of reduction is looked upon as mathematical rather than therapeutic, there will, indeed, be suffering enough. Rightly handled there is very little. Three-fourths of my patients say that they are more comforftable under my care than when taking the drug themselves. Others still advocate the quick methods because they are easy to apply—a poor reason. Certainly the patient who has gained forty pounds by the time the last dose is withdrawn is in better shape to withstand the dangers of relapse than one who has lost twenty pounds while undergoing the trying ordeal of a quick method of treatment and whose nerves are wracked to pieces.

I do not recommend this system of treatment as one that any tyro can pick up and handle successfully. Its technique must be mastered by close clinical study, preferably under the instruction of one who is master of all the details.

## THE PROTEIN ELEMENT IN NUTRITION.

FOR many years the question of the amount of protein necessary for the proper nutritional support of the body was considered as definitely determined, an opinion based chiefly upon the studies of Voit. Chittenden, however, in a long and careful series of dietary experiments showed some years ago that it was perfectly possible for persons living a sedentary life to cut down the amount of protein intake without interfering with comfort or mental or physical activity. Chittenden's experiments were very carefully performed and no question has been raised as to the accuracy of the analytical determinations or the reliability of the facts reported. There has been, however, a great deal of criticism as to the general applicability of such a limited diet, either in health or in disease, and Chittenden himself has acknowledged that not everyone is capable of reducing protein intake to or below eight grams of nitrogen a day, and still retaining a satisfactory physical condition. The discussion has been carried on from several standpoints; some have tried to argue from the excellent results obtained by overfeeding in tuberculosis and similar conditions that a reduction in the total protein of the food would make persons more liable to infections; others have pointed to the universal consumption of large quantities of meat by the well-to-do classes and the excellent physical condition of persons living under such conditions.

The experiments of Chittenden were open to attack from one point, that of necessity the period over which they extended was limited. Only a few of the experimenters continued on a five to six gram nitrogen diet for more than a year or so. It was evident, therefore, that the question must be studied by comparing people who had been for a number of generations on such a diet with those on a high protein food during the same period. Major D. McCay, the writer of a recent monograph on this subject,* by reason of his official position in India, has had unusual opportunities in the study of races who have for generations lived on a low protein régime, since among some of the native tribes the protein intake is very small, while among others meat is largely eaten, and in far greater quantity than the European average. While details cannot be given here the general conclusions as stated in this little volume are that a diet fairly liberal in protein does not necessarily carry with it the penalties which Chittenden thought might be due to an excess of nitrogen excretion, but that the healthiest and best-developed races in Hindustan are those that consume the largest quantities of protein. The question cannot yet be regarded as closed, but this monograph is a very interesting and valuable contribution to the high protein side of the problem by a man whose opportunities for observation have been exceptional.

*The Protein Element in Nutrition. By Major D. McCAY, M.B., B.A.O., M.R.C.P., I.M.S. Professor of Physiology, Medical College, Calcutta. (International Medical Monographs.) Price, $3.00 net. London: Edward Arnold; New York: Longmans, Green & Co., 1912.

## VACCINE THERAPY OF PERTUSSIS.

LIKE others of the so-called diseases of childhood, pertussis is too often regarded as a matter of small moment and its really serious possibilities are not considered. Yet in gross mortality it exceeds scarlet fever and diphtheria. In children it takes first rank among the acute infections as a cause of death. Especially under one year of age is it to be dreaded, and in institutions the mortality in infants ranges from 25 to 50 per cent. It is particularly dangerous in infants because of its common and serious complications of bronchopneumonia, convulsions and gastroenteritis. A large percentage of the deaths from the disease follow the complicating bronchopneumonia. In the United States for 1910 whooping cough had a death rate of 11.4 per 100,000 population, while the death rate from scarlet fever was 11.6 per 100,000, of measles 12.3, and of diphtheria 21.4. Thus it is seen how evidently whooping cough ranks with the most dangerous diseases of childhood. In spite of its extreme communicability and serious nature especially in infants and young children, the physician is prone to underestimate its danger. Yet as Rucker, writing in Public Health Reports, No. 100, pointedly states, "Any disease which kills 10,000 children per annum is a serious disease. If bubonic plague were to kill that many children in the United States in one year, the whole world would quarantine against our country. A child dead of whooping cough is just as dead as if it died of plague. Whooping cough is a disease to be avoided and combated in the interests of humanity and the citizens of to-morrow."

Until Bordet and Gengou in 1906 discovered a presumptive cause for pertussis, the etiology was frankly hidden and little progress was made toward securing a specific remedial agent. Bordet and Gengou assigned an etiological rôle in pertussis to a bacillus which they isolated from the deeper and more remote parts of the respiratory tract. It is seldom found above the level of the larynx and oftenest is below it. This bacillus is small, ovoid non-motile, Gram-negative, and takes feeble stains with the ordinary basic stains. It grows best on a mixture of 3 per cent. agar with defibrinated rabbit or human blood. The discovery of this bacillus has led investigators to seek a specific therapeutic agent for pertussis.

Bamberger in the January number of the *Ameri-*

*can Journal of Diseases of Children* reports six cases of whooping cough treated with autogenous vaccines of the Bordet-Gengou bacillus. This bacillus was isolated by plating and replating cultures made from deep swabs of the throats of children suffering from the disease. The vaccines contained twenty millions of the dead organisms per c.c., and were made from several strains of bacilli in order to obtain polyvalency. The children, ranging from 1 to 4 years in age, showed no constitutional symptoms from the injection of vaccine. Bamberger concludes that the treatment seemed rather to lessen the severity and abort complications, than to shorten the duration of the disease, although only two of the cases lasted six weeks. The sooner the treatment begins, the better the results. He recommends large doses of 500 millions of the organisms administered daily and considers that the method may do much good and in any case will do no harm.

Such work deserves encouragement and this subject should receive full and careful laboratory investigation. To place the treatment of pertussis on a par with that of diphtheria will be a splendid achievement. The problem is attracting well-deserved attention and we may hope for a speedy solution.

## PROGERIA AND ATELEIOSIS.

Both of these terms have been introduced into medical nomenclature by Hastings Gilford. Progeria, which means premature old age, has been used to designate those extremely rare cases of infantilism in which, in addition to the arrest or delay in the growth of the body, there also develops a condition of premature senility. From a childhood that has been delayed in development the individual passes into a premature old age. Ateleiosis is the name given to an important variety of infantilism for which no apparent antecedent or coexisting cause can be assigned. It is a retardation rather than an arrest of development. It may begin at any period of the life of the individual, it may affect different parts of the body to a different degree, and its rate may vary in different cases.

Prof. Arthur Keith of the Royal College of Surgeons of England reports in the *Lancet,* February 1, 1913, the results of a study that he has made of the skeleton of a case of progeria, which skeleton has recently been added to the museum of the college. He describes in detail the peculiar combination of infantile and senile changes manifested in the skeleton. He also points out the striking contrast between this condition and acromegaly. Those parts of the skeleton which are overgrown in acromegaly are undergrown in progeria. Progeria is not a generalized dwarfism, nor is acromegaly a generalized overgrowth of the bones of the body. Both conditions are selective in action and affect the same tissues and parts of the body. It is noted that Gilford regards progeria and acromegaly as contrasted forms of senilism. In progeria the tissues pass prematurely into the condition seen in aged men and women; in acromegaly the tissues undergo an atavistic change and assume characters belonging to a remote phase in the evolution of the human body; in other words, acromegaly is a condition of ancestral senilism.

Keith, without committing himself as to the validity of this hypothesis nevertheless perceives an important contrast between acromegaly and progeria as regards the light they throw upon the physiology of the internal secretions. It is suggested that if the changes in acromegaly are produced by a stimulus or hormone proceeding from the hypophysis cerebri, then the condition in progeria can be best explained by an absence or marked diminution of that stimulus.

## TUBERCULOSIS IN CHILDHOOD.

This subject is frequently revised to date, and many are the new notions introduced which do not stand the test of time. Most of these innovations revolve about individual conceptions of scrofula. One would see in the latter chiefly "pyogenic" manifestations, in which only the ordinary pus exciters are involved—pyogenic scrofula of Cornet. Another sees in the old clinical conception of scrofula the modern exudative diathesis, or the status thymicolymphaticus. A third makes no distinction between the almost universal lymphadenopathy of childhood and actual tuberculosis—the enlarged lymph nodes standing for latent tuberculosis or representing a paratuberculosis.

If we exclude from consideration all doubtful lesions and adhere throughout to manifest tuberculosis of the sort which attacks adults, we obtain clear-cut results. Thus Rohmer during a session of the General Medical Society of Cologne (*Münchener medizinische Wochenschrift,* January 21), gives a chronological scheme of acquired infantile and child tuberculosis as follows: During the nursling period we may have a primary focus in the lung, with consecutive involvement of the bronchial lymph nodes with eventual caseation. There is no tendency to local or general extension at first, but from the caseous deposit a generalized tuberculosis may result within the year. From the second to the sixth year the meninges are most frequently secondarily involved, and there will be many more cases of tuberculous meningitis than of generalized tuberculosis. Osseous and glandular lesions are also of common occurrence (meaning, of course, manifest cases of tuberculosis of internal origin). During the same period acute miliary tuberculosis and acute caseous pneumonia are not uncommon. We must reach the school years—say from six to fourteen, inclusive. These years are characterized by an extremely low tuberculous morbidity and mortality. In other words, what the French term the "second childhood" (second dentition to puberty) is one of relative immunity to the disease. Roughly speaking, the caseous bronchial lymph nodes of the nursling represent the primary stage, and the numerous and varied manifestations up to the school years are the secondary manifestations. Then after a latent period we see first develop at puberty chronic pulmonary tuberculosis—a truly tertiary symptom, which becomes such a scourge to the race in its later years.

### On Anaphylatoxins and Endotoxins of the Typhoid Bacillus.

This is the title of an interesting paper in the *Journal of Experimental Medicine,* February 1, 1913, by Hans Zinsser, whose investigations go a great way toward explaining the toxemic manifestations of typhoid fever. His own and other recent work shows that it is not necessary to assume that bacterial toxemias are the result of the presence of specific endotoxins in the bacteria. Friedberger has demonstrated that acutely toxic bodies can be produced from typhoid bacilli by the action of sensitizer and complement, and that when small quantities of bacteria are used an excess of sensitization either interferes with the formation of the poisons or leads to a cleavage of the bacterial protein beyond the poisonous intermediate products spoken of as anaphylatoxins. These results have been confirmed by the experiments of Zinsser. But he has also shown, and in this respect his results differ from those of other investigators, that the action of complement upon typhoid bacilli, strongly sensitized or not at all sensitized, may be carried on at body temperature for considerably longer than twelve hours without leading to a destruction of the poisons, and that this is true when the quantities of the bacteria used vary within the wide range of from one to twelve agar slants. Powerful poisons are obtained by prolonged exposure at the higher temperature of considerable quantities of bacteria. From these experiments it is concluded that complement action of considerable vigor is required to obtain from the typhoid bacillus any appreciable yield of anaphylatoxin. The conditions prevailing in the infected body at the height of typhoid fever are those that favor the production of anaphylatoxin, the large number of sensitized bacilli being under the prolonged influence of considerable quantities of complement. It is suggested that while the existence of preformed intracellular poisons as an element in typhoid toxemia has not been proved, nevertheless poisons of this nature may still play a rôle in this disease, as perhaps in the production of the diarrhea and the hemorrhagic lesions.

### The Phenomenon of Arthus in Diphtheria.

Arthus's phenomenon is defined as a manifestation of anaphylaxis in which a guinea-pig, after receiving several injections of normal horse serum, develops an abscess, edema, or gangrene at the site of the last injection, becomes cachectic, and dies. In *Le Bulletin Médical,* January 18, 1913, Aviragnet and Hallé report four cases of diphtheria in which the serum treatment was followed by the gangrenous type of this phenomenon. They note that this extremely rare form of reaction occurs only when certain etiological conditions are present, as in the cases they report. These conditions are the following: (1) The injection of the antitoxic serum on the ventral surface of the body; (2) the recent occurrence of an eruptive fever, such as measles, scarlatina, or varicella; (3) the presence of diphtheria during its period of evolution, and (4) the presence of a severe grade of infection. In the cases observed by the authors there followed almost immediately after the injection of the antitoxic serum into the subcutaneous tissue of the abdomen a hemorrhagic necrosis of the skin. In two of the cases this was localized to a small area around the point of inoculation, but in the other cases it spread all over the abdomen and over the thighs. All of the cases terminated fatally. The lethal outcome was anticipated in two of the cases even before the antitoxic serum was administered, for the diphtheritic infection was a most virulent one. In the remaining cases the cutaneous gangrene superadded to the orginal infection made recovery impossible. The history of these cases, however, should not deter one from employing antitoxin when this is indicated, for the phenomenon of Arthus is of extremely rare occurrence and may be disregarded in the routine serum treatment of diphtheria.

## News of the Week.

**City Housecleaning.**—In a recent letter to the Mayor, Commissioner Lederle proposes a spring housecleaning for all of New York City, to the end that the city may be cleaner and healthier than ever before. The Commissioner suggests the removal of rubbish and dirt from cellars, yards, and vacant lots, through cleaning of the streets, cleaning out of garbage pails, freeing the city as far as possible from smoke and cinders, fighting the fly and the mosquito, not by "swatting" but by preventing breeding, and various other ways of promoting cleanliness and consequently health. The Mayor has approved the suggestion and has promised the cooperation of the various city departments.

**Immunization against Typhoid.**—The Department of Health of New York City has issued a brochure of information regarding immunization against typhoid fever, a procedure which the Department is now prepared to perform on request under conditions similar to those governing the free administration of diphtheria antitoxin. Inoculations will be made by the Department inspectors at the homes of applicants upon the advice of the attending physician, or cultures will be furnished directly to the physicians, or inoculations will be made at the Central Office in the Borough of Manhattan after investigation of the cases. The cultures used are prepared in the research laboratories of the Department.

**Regulating Vivisection.**—Still another bill aiming to regulate vivisection was introduced into the New York State Senate on February 10. The measure provides for the appointment of a board of supervision by the State Board of Regents from a list of names presented by any corporation of the State having as one of its objects the prevention of cruelty to animals. The size of the board of supervision is left to the discretion of the Regents.

**City Death Rate.**—For the week ending February 8, the death rate in New York City was 15.23 per thousand as against 15.24 for the same week of 1912, although the total number of deaths was increased from 1511 to 1568, this increase of 57 being offset by the estimated increase of population. The deaths from diphtheria, croup, and influenza were materially increased, while those from measles, scarlet fever, and typhoid fever were decreased in number. The death rate for the first six weeks of this year was 14.64 per thousand, as compared with 15.31 for the corresponding period of 1912.

**Report from Canal Zone.**—During the month of December, 1912, the death rate per thousand,

among the employees of the Isthmian Canal Commission was 7.14, a decided decrease as compared with 10.42 during the same month of 1911. Among the entire population of the cities of Panama and Colon, and the Canal Zone, the death rate per thousand was 20.99, a slight increase over the preceding year. Of the 32 deaths among employees, 9 were due to violence and 23 to disease, and of these 6 were due to lobar pneumonia and 6 to tuberculosis. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

**South Carolina Medical College.**—The Legislature of South Carolina recently passed, without a dissenting vote, the bill transferring the Medical College of South Carolina to the State in trust to control and operate. The management of the college is vested in a board of the Governor, the Superintendent of Education, the chairmen of two committees, and eight other members to be elected by the Legislature. An appropriation of $20,000 for the reorganization and continuance of the work during the present year is included in the bill.

**The Split Fee.**—A bill recently introduced into the Missouri State Legislature makes it unlawful for any physician or surgeon to divide a fee received from a patient, and imposes as a penalty the revocation of the offender's license and a fine of five hundred dollars. The bill also authorizes the State Board of Health to revoke the licenses of physicians addicted to the use of alcohol or drugs, or who are of immoral character.

**Fake Drugs.**—Dr. Carl L. Alsberg, the recently appointed head of the Bureau of Chemistry, made his first public statement of policy in a speech before the National Association of the Manufacturers of Medical Products in New York on February 12. The most important immediate duty of the bureau is, in his opinion, the curbing of traffic in worthless nostrums between the States. The efforts of the Department in controlling the adulteration of food products have been attended by considerable success, but this is not true of the attempts to regulate the sale of patent medicines, although it has been possible to bar the importation of all those bearing false or misleading labels as to curative power. With the domestic drugs many ways have been found of evading the law, but there is hope in the Sherley Act and also in the movement spreading among the decent newspapers and periodicals to bar from their advertising columns all but clean and honest matter. Dr. Alsberg also declared his intention of using every means at his command to stamp out the circulation of habit-forming drugs, such as opium and cocaine.

**The Friedmann Culture.**—Recent reports from Germany state that Dr. F. Friedmann has at lengthi carried out his promises and has given some of his alleged tuberculosis cure into the hands of Dr. Paul Ehrlich for test purposes. Dr. Friedmann himself is said to have sailed on February 18 for the United States, where better financial returns may be hoped for, if he proves his case, than at home. The publicity given to his claims by the newspapers has, as is always the case, resulted in a pitiful rush of sufferers to Berlin, with consequent disappointment. Up to the present, Dr. Friedmann's claims rest only on his unsupported word.

**Hospital to Sell.**—The building and site of the New York Nursery and Child's Hospital at Lexington avenue and Fifty-first street, are to be sold at auction on March 12. For the present, the hospital will continue its work in the building at Amsterdam avenue and Sixty-first street, but with the proceeds of the sale a new site will probably be obtained and improved quarters erected. The present site, lying as it does within the zone affected by the changes in the New York Central terminal, has become very valuable.

**Home for Aged.**—A bill has been introduced into the New York State Legislature providing for the establishment of a home for the aged of both sexes in the southern section of the State. An appropriation of $100,000 for a five-hundred acre site and for the erection of suitable buildings has been requested. The home, from which it is intended to remove all stigma of pauperism, will draw its inmates chiefly from New York City and Westchester and adjacent counties.

**Children's Hospital.**—St. John's Hospital, the new department of the Roman Catholic Orphanage, New York, was formally dedicated by Cardinal Farley last week. The building is four stories high, with a playground on the roof, and has accommodations for thirty children.

**Meningitis in Legislature.**—The sudden death of two Representatives in the Texas Legislature and the serious illness of a third, from cerebrospinal meningitis, caused the adjournment of that body on February 15.

**Physicians Licensed.**—Of the fifty-eight physicians who took the examination of the Virginia State Board of Medical Examiners recently, for license to practice in the State, forty-two were successful. Among these were two colored women, who thus become the first women of their race to be admitted to practice in Virginia.

**New Medical School.**—After careful planning, the trustees of the University of Chicago have announced their intention of erecting on the University grounds a magnificent group of buildings in which to house a medical school second to none. The Rush Medical College, already affiliated with the University, will be absorbed by the new institution for which a large endowment is being sought among the friends of the University.

**Dr. Alexis Carrel** of the Rockefeller Institute, New York, has been made a chevalier of the Legion of Honor of France.

**Cartwright Lectures.**—As previously announced, Prof. Ludwig Aschoff will deliver the Cartwright Lectures of the Association of the Alumni of the College of Physicians and Surgeons, New York. There will be two lectures, the subjects being "Thrombosis" and "Contracted Kidney," and they will be given at the New York Academy of Medicine on March 12 and March 15.

**Surgeon Seeks Pay for Aiding a Confrère.**—The Appellate Division of the Supreme Court of New York recently reversed the judgment of a lower court and ruled that when a physician is called upon by another to aid in an emergency case, the law will not award payment for his services. In this case a surgeon on the attending staff of a hospital in New York was performing an operation when the patient was seized with a severe hemorrhage, and the operator requested the assistance of another member of the attending staff, in checking the hemorrhage and completing the operation. The first physician had agreed before the operation to accept a fee of ten dollars from the patient, and therefore refused to pay a bill of twenty-five dollars presented by the second for his services. A suit in the Municipal Court followed with an award

for the amount claimed, and it is this decision which the Appellate Division has just reversed. Justice Lehman, who wrote the opinion, says: "If the plaintiff is entitled to recover it must be upon the theory that no professional courtesy or duty requires a physician to give aid to a brother practitioner associated with him in the same hospital, where the brother practitioner's skill is insufficient to cope with an emergency that has arisen and may cause disastrous results to the patient under his care. I am absolutely unwilling to hold that the profession of medicine does not impose such an obligation upon its members."

**Semicentennial of the New York Obstetrical Society.**—On Friday, February 14, 1913, there was held at the University Club, New York, a dinner at which there were about ninety present, to celebrate the Fiftieth Anniversary of the founding of the New York Obstetrical Society. Dr. George G. Ward, Jr., acted as toastmaster. There were present as guests of the Society: Drs. Abraham Jacobi, Matthew D. Mann of Buffalo, E. P. Davis of Philadelphia, Edward Reynolds of Boston, Frank Simpson of Pittsburgh, G. M. Boyd of Philadelphia, Wm. P. Sprigg of Washington, and Albert M. Judd of Brooklyn. Portraits of Dr. Thomas Cock, the first President of the Society, Dr. J. Marion Sims, Dr. Edward R. Peaslee, Dr. T. Addis Emmet, Dr. T. Gaillard Thomas, Dr. Wm. C. Lusk, Dr. Alexander J. C. Skene, Dr. Emil Noeggerath, Dr. Paul F. Mundé, and Dr. Josiah Knox were shown on the screen. A brief history of the Society was given by Dr. J. Riddle Goffe and Dr. Wm. S. Stone. Addresses were also made by Drs. E. P. Davis, Edward Reynolds, J. Whitridge Williams and A. Jacobi.

**State Medical Association of Texas.**—The date of the annual meeting of this Association has been changed from May 13-15 to May 6-8.

**Charitable Bequests.**—By the will of the late Dr. James P. Tuttle of New York, the New York Academy of Medicine receives a bequest of $1,000 to establish a fund for the purchase of books and literature referring to diseases of the alimentary tract.

By the will of the late Mr. John M. Lohse of New York a bequest of $10,000 is made to the Presbyterian Hospital and one of $15,000 to the German Hospital, while the Mount Vernon Hospital receives the sum of $8,000.

St. Catherine's Hospital and the German Hospital, Brooklyn, receive bequests of $5,000 each under the will of the late Mr. Louis Bossert of that city.

**Federation of State Medical Boards.**—The annual convention of this society will be held at the Congress Hotel, Chicago, Ill., on Tuesday, February 25, 1913, under the presidency of Dr. Arthur B. Brown of New Orleans. The secretary is Dr. George H. Matson, State House, Columbus, Ohio.

**Prof. Jaques Loeb** will read a paper before the Manhattan Medical Society on Friday evening, February 28th, at 8:30 o'clock, entitled "Some Recent Experiments on Artificial Parthenogensis." The officers of the society are Benjamin T. Tilton, *President;* William H. Stewart, *Vice-President;* Harold Hays, *Secretary*, and Albro R. Carman, *Treasurer.*

**Obituary Notes.**—Dr. George Clinton Jeffery of Brooklyn, N. Y., a graduate of the Pulte Medical College, Cincinnati, O., in 1875, a member of the American Institute of Homeopathy and of the New York State Homeopathic Medical Society, and consulting surgeon to the Cumberland Street, Memorial, and Jamaica Hospitals, died at his home on February 11, aged 61 years.

Dr. Helen Paschall Proctor of Philadelphia, a graduate of the Woman's Medical College of Pennsylvania, in 1905, died at her home on January 23, aged 41 years.

Dr. Edgar C. Quimby of Titusville, Penn., a graduate of the Cleveland University of Medicine and Surgery in 1881, died at his home on January 25, aged 57 years.

Dr. Thomas Henry McNally of Central Falls, R. I., a graduate of the University of Vermont College of Medicine, Burlington, in 1886, and formerly mayor of Central Falls, died suddenly at his home on January 24.

Dr. Francis F. Corson of Bridgeton, N. J., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1869, and a member of the New Jersey State and Cumberland County Medical Society and former president of the latter, died suddenly on February 1, aged 65 years.

Dr. Henry Goodwin MacKaye of Newport, R. I., a graduate of Harvard University in 1878 and of the Harvard Medical School, Boston, in 1885, a member of the Rhode Island State and Newport District Medical Societies, and for many years on the staff of the Newport Hospital, died at his home on February 2, aged 57 years.

Dr. George Washington Jenckes of Woonsocket, R. I., a graduate of Brown University in 1851 and of the Harvard Medical School, Boston, in 1854, a member of the Rhode Island State and Providence District Medical Society, and at one time president of the former, and president and later president emeritus of the Woonsocket Hospital, died at his home on January 26, aged 83 years.

Dr. Augustus R. Wright of Lumpkin, Ga., a graduate of the Atlanta College of Physicians and Surgeons in 1900, and a member of the Georgia State and Stewart-Webster Counties Medical Societies, died on January 29, in Brooklyn, N. Y., where he had gone for medical treatment, aged 45 years.

Dr. David W. Jump of Plainfield, Ill., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1872, and a member of the American Medical Association and the Illinois State and Will County Medical Societies, died suddenly on January 29, aged 65 years.

Dr. Benjamin F. Graham of Minneapolis, Minn., a graduate of the Starling Medical College, Columbus, O., in 1865, and a member of the American Medical Association and the Minnesota State and Hennepin County Medical Societies, died suddenly at his home on February 2, aged 73 years.

Dr. Eli J. Smith of Neenah, Wis., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1878, and a member of the American Medical Association, and the Wisconsin State and Winnebago County Medical Societies, died at the Clark Memorial Hospital after a short illness on January 31, aged 57 years.

Dr. Arthur Stanford Fletcher of Waterville, Me., a graduate of Tufts College Medical School, Boston, in 1906, and a member of the Maine State and Kennebec County Medical Societies, died at his home on January 31 from typhoid fever, aged 31 years.

Dr. Elmer E. Moore of East Providence Center, R. I., a graduate of the Dartmouth Medical School, Hanover, in 1886, and a member of the American

Medical Association and the Rhode Island State and Providence District Medical Societies, died at his home after a short illness on January 30, aged 52 years.

Dr. Samuel Whitfield Hartt of Seattle, Wash., a graduate of the College of Physicians and Surgeons, Baltimore, in 1889, died at his home after a long illness on February 5, aged 48 years.

Dr. Alfred G. Abdelai of Kansas City, Mo., a graduate of the Université de Montpellier, France, in 1852, a veteran of the Civil War and of the Franco-Prussian War, and a surgeon in the army of Maximilian during the invasion of Mexico, died at his home on January 25, aged 80 years.

Dr. Robert Parkers Mars Ames of Springfield, Mass, a graduate of the Jefferson Medical College, Philadelphia, in 1880, a member of the American Medical Association and of the Massachusetts State and Hampden County Medical Societies, and formerly a surgeon in the United States Navy, died at his home recently, aged 56 years.

Dr. Lewis W. Steinbach of Philadelphia, Penn., a graduate of the Jefferson Medical College, Philadelphia, in 1880, professor of surgery in the Philadelphia Polyclinic and College for Graduates in Medicine, and a member of the American Medical Association, the Pennsylvania State and Philadelphia County Medical Societies, and the Philadelphia Academy of Surgery, died at his home from pneumonia on February 10, aged 62 years.

Dr. Edward Sanford of Attleboro, Mass., a graduate of the Harvard Medical School, Boston, in 1852, died at his home after a short illness on February 5, aged 87 years.

Dr. Parks Ritchie of Saint Paul, Minn., a graduate of the Medical College of Ohio, Cincinnati, in 1870, professor of obstetrics and gynecology in the University of Minnesota, College of Medicine and Surgery, and formerly dean of the college, and a member of the American Medical Association, and the Minnesota State and Ramsey County Medical Societies, died at his home suddenly on February 2, aged 67 years.

Dr. Ulysses P. White of Artesia, N. M., a graduate of the College of Physicians and Surgeons, Baltimore, in 1894, died at his home on February 4, aged 44 years.

Dr. Isaac W. Douglass of Michigantown, Ind., a graduate of the Cincinnati College of Medicine and Surgery in 1864, a member of the Clinton Medical Association, and a veteran of the Civil War, died at his home from pneumonia on February 3, aged 72 years.

Dr. Edward L. Washburn of New Haven, Conn., a graduate of the Medical Department, Yale University, in 1865, died at his home from arteriosclerosis on February 10, aged 73 years.

Dr. William Beattie Nesbitt of Toronto, Ont., a graduate of the University of Toronto, Faculty of Medicine, in 1888, died at his home after a long illness on January 31, aged 45 years.

Dr. William F. Ganster of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1896, and a member of the American Medical Association and the New York State and Kings County Medical Societies, died at his home, following a nervous breakdown, on February 11, aged 46 years.

Dr. J. F. Flynn of Humboldt, Kan., a graduate of the Chicago Homeopathic Medical College, in 1893, died at his home after a short illness on February 1, aged 50 years.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPERATIVE SURGERY IN GENERAL PRACTICE—ACTINOMYCOSIS—SANITARY ENGINEERING—NOTIFICATION OF TUBERCULOSIS—DEPARTMENTS FOR HOSPITALS RECOMMENDED—LIVERPOOL TROPICAL SCHOOL—INQUESTS—OBITUARY.

London, Jan. 31, 1913.

General practitioners in this country are as a rule much less disposed to undertake surgical operations than is the custom on your side. In the cities and large towns there are hospitals to which the poor naturally go and many who have not that title to charitable help and would be willing to pay moderate fees seek admission because they cannot afford to engage a pure consulting and operating surgeon. For this and other reasons it has become customary for the majority of practitioners to give up operative work. There are, however, many who are willing and able but whose position does not give them much opportunity to exercise their skill in surgery. In serious cases a second opinion is asked for by the patient or his family or may be desired by the practitioner himself and then the operation, if decided on, naturally falls to the consulting surgeon called in and if the patient cannot pay his fee he may gain admission to his hospital. Mr. T. North, who is a practitioner ready to undertake what surgery comes in his way, brought the subject before the Medical Society of London and advocated the recognition of a class which he called "practitioner-surgeons," who for moderate fees would be willing to cooperate with those of their neighbors who preferred other work. There is really no need to set up a sort of specialty. Almost every G. P. has a surgical diploma giving full recognition and in many towns one of them possesses the confidence of his neighbors. In the present state of the profession the point deserves consideration and Mr. North's account of his own practice is most interesting. He showed the difference of operating in a private house and a hospital theater and insisted on the minutest attention to detail. To a man just coming from a modern, well-equipped hospital, where every assistance was waiting for him, it might look impossible to operate without any surgical conveniences, but it was not. He might scorn to see a kitchen pot or a fish kettle taking the place of a high pressure sterilizer, but they had served effectually in a pinch. He would not recommend aseptic work to a beginner for use in private practice for it is more likely to break down than antisepticism and involves great initial expense. Further, sepsis is much less likely to occur in private practice than in hospitals. Mr. North's results supported his opinions. He was able to report between 700 and 800 operations, including the most important, with a mortality of 2 per cent. for the whole series and 4 to 6 per cent. for abdominal sections.

Actinomycosis has been before the surgical section of the Royal in a couple of interesting papers. Mr. Haynes Lovell read one with special reference to involvement of bone based on a case which began as it usually does in the lower jaw. There was toothache at first and extraction of a bicuspid, and then a molar was done but no disease found in either. Some ten days later a swelling appeared in connection with the jaw externally and advanced

to the size of a walnut with no sign of disease in the mouth. A skiagram showed rarefaction, suggesting abscess at the root of first bicuspid but no sign of new bone or periostitis. Incision let out a little pus without organisms, but a culture grew a streptothrix. An autogenous vaccine was used, the bone scraped, and potassium iodide given in large doses with success. Mr. Lovell remarked that bone disease was usually an extension from the soft parts, primary disease in man only observed in the jaws probably infected through sockets of carious teeth. Two cases of isolated foci had been reported, one in lower end of the femur, the other in upper end of the tibia. There might be (1) periostitis due to adjacent disease of soft parts; (2) peripheral rarefaction (rare); (3) a central perforating type, the usual one in man (as in case above); (4) a central neoplastic type, common in cattle.

Mr. T. H. Kellock read the second paper, in which he considered the clinical features as observed in his own cases. Actinomycosis he met in two conditions, simple and septic—in the latter it was difficult to demonstrate the organism. The infection was almost always through the alimentary or respiratory tracts. Once within the cavities of the body it had a tendency to insinuate itself into the ducts opening on the surface and thus it affected the salivary glands, liver, and appendix vermiformis. It rarely spread by the lymphatics but mostly by continuity of tissue, unlike tuberculosis, ignoring anatomical boundaries. In the lower jaw its most marked feature was its painlessness in comparison with septic infection. A small, red, puckered spot on the face, perhaps preceded by a toothache, enlarged and was found adherent to bone. It softened and if incised very little pus escaped. If small and isolated it might get well without treatment beyond incision. He had not seen it in the upper jaw. Infection of glands opening into the mouth was common. In two cases he had known it to affect the tongue without any surface ulcer—a soft, painless swelling of rapid growth interfered with the movements of the organ—when it attacks the tissues at the side of the neck it causes marked fixation and spreads backwards sometimes as far as the spine. When the lung is the primary seat adhesion to the chest wall occurs rapidly. Chronic abscess at any part of the wall is found. In the appendix and cecum there is much infiltration, which, if abscess forms, lifts up the iliac vessels and infects the psoas muscle. In one of his cases the right kidney was attacked and removed under the impression that it was tuberculous as the patient had pyuria and pyrexia. Recovered after long course of potassium iodide in large doses. In all his cases diagnosis was confirmed by bacteriological examinations. He summed up the chief features as comparative painlessness, linear puckering of skin, spreading by infiltration of surrounding parts with no regard to tissue, entering ducts opening on mucous surfaces, little pus from considerable swelling, rapid improvement after scraping and potassium iodide in full doses, and little deformity or disfigurement remaining after eradicating by efficient treatment.

At the Institute of Sanitary Engineers Mr. H. P. Boulnois, in his presidential address last week, pointed out that many improvements in the removal of dry waste products still required to be carried out for notwithstanding some advances in temporary storage of house refuse and its ultimate disposal by burning, the objectionable method of collecting it was the same as forty years ago. He also spoke of the housing of the lower class and the way in which the efforts of sanitary engineers are thwarted by the habits of the people. Advances had been made in the ventilation of public buildings but there was scope for further progress. As to town planning of which so much is being heard, the first principle was proper designing of water supply and sewerage, involving very careful leveling and contourage; then roads, open spaces, houses, schools, hospitals, and other necessary provisions concerning all of which overcrowding should be kept in mind for the ignorance of the masses as to health was lamentable.

Tomorrow the revised order respecting the notification of tuberculosis is to take effect. It consolidates and extends the previous orders of 1908 and 1911 amending some points. By this order compulsory notification is extended to all cases of tuberculosis instead of pulmonary ones only as heretofore. The practitioner who first diagnoses its existence is required to notify immediately the health officer of his district and will be paid a fee of 2s. 6d. for the certificate.

The Council of the Royal College of Surgeons has adopted resolutions of a special committee recommending hospitals to establish a department for tuberculosis; to consider the advisability of applying for provisional approval as regards sanatorium benefit, and in localities where possible of utilizing the services of consulting physicians and surgeons under the Insurance Act in tuberculous cases.

The University of Liverpool has appointed Dr. J. W. W. Stephens to the Alfred Jones professorship of tropical medicine in succession to Sir Ronald Ross. Dr. Stephens has held the Myers lectureship on this subject for the last ten years.

Coroners' inquests are being reported on "victims to the Insurance Act" and even under more alarming terms. It is generally alleged that the deceased insured person could not obtain the attendance of the panel doctor because he was overburdened with the work—mostly filling up the schedules. Coroners have commented freely on these cases. In one the evidence was that more than 100 patients were waiting to be attended to. It seems curious that so many persons should be taken ill as soon as they were entitled to free attendance and that one surgery should be so overcrowded while other panel men were within a stone's throw.

A sadder case is that of a doctor who was said to have died from overwork in writing up the statistics of his panel work. Dr. Ducket, of East Ham, was found unconscious on his round, taken home and died. At the post mortem cerebral hemorrhage was discovered. The doctor who made it gave evidence and said he knew deceased was worried over the act and in fact had told him the previous day it was killing him. The widow confirmed this and added that he said it would be his death just before he went out. She also declared that they had sat up until a quarter to two every morning on the books of the panel work. Replying to the coroner she repeated that it was a quarter to two every morning when they turned out the gas.

Dr. J. M. Barnett, late surgeon-major of the Indian Army, died on the 24th inst. at the age of 82. He served and was wounded in the Persian campaign and received the medal with two clasps. He was also through the Indian mutiny. He was

M.D. Edin, 1852, in which year he joined the service. He retired in 1869 and had devoted himself to work in connection with various missions and social efforts.

Dr. Rudkin, consulting surgeon to Teignmouth (Devon) Infirmary and holding other appointments, died on the 27th inst.

Dr. Livesay died on Jan. 24 in the Isle of Wight after a long illness at the age of 68. He took M.D. Edin. in 1875. He edited "Yachting in the Arctic Sea." He had been president of the Royal Medical Society. He retired invalided about three years ago.

Dr. Owen T. Williams, Registrar Liverpool Royal Infirmary and lecturer on pharmacology at the University, holding several other appointments, died on the 15th inst. at the early age of thirty-two. He was joint editor with Professor B. Moore, of "Researches in Bio-Chemistry," a subject on which he had worked in the Johnston Laboratory. He also contributed numerous papers to the scientific side of medicine. He was B.Sc. and M.D. Lond.

Dr. Joseph Bayley, medical superintendent of the Hospital for Mental Diseases at Northampton, died on the 19th inst., aged 77.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

THE PLAGUE—EMERGENCY MEDICAL RELIEF—TRANSFER OF LEPERS FROM GUAM—DIPHTHERIA—PERSONAL.

MANILA, P. I., December 21, 1912.

PLAGUE is still present in Manila, a few cases occurring from time to time. At Iloilo there have been no cases since September. There are many facts in connection with the outbreak of plague at Iloilo that would indicate that the disease was transmitted by bedbugs. All of the cases occurred in two houses, and after a diligent rat campaign extending over a period of three months, no plague rats have been found.

Since the beginning of the outbreak in Manila during June, there have been 49 cases with 41 deaths. During the past few weeks the disease has made its appearance in the Walled City, which is on the south side of the Pasig River, upon which side no cases had heretofore occurred. The first case that came to the attention of the health authorities was that of a cat which was kept in the commissary storehouse of the United States Army, and almost coincidently, human cases began to occur. Plague infected rats have also been found. It has now been a number of months since there have been any cases in the sections of the city which were first affected.

The recent severe typhoons which have swept through the southern islands of the Philippine Archipelago have made it necessary to provide considerable emergency medical relief to the victims. Upon receipt of information of the Cebu typhoon, five medical officers of the Bureau of Health, three medical officers of the United States Army, six Hospital Corps men, and a number of nurses, were sent to the stricken district. The haste with which this expedition had to be started gave an excellent illustration of the preparedness of the Insular Government to cope with emergencies. Information that medical relief was needed was not received until 11 o'clock in the morning of October 19, and at 4 o'clock in the afternoon of the same day, a vessel with the above-mentioned personnel and complete surgical equipment and necessary medicines, food supplies, tents, etc., was en route to the typhoon district. To aid the victims of the typhoon which occurred during the latter part of November, and of which Tacloban was the center, a number of medical officers were sent, and considerable relief was extended to towns in the provinces of Samar and Leyte.

In accordance with a recent act of Congress, the lepers of Guam, twenty in number, were transferred to the Culion leper colony. The Navy Department, under the jurisdiction of which Guam falls, will reimburse the government of the Philippine Islands for the expenses in connection with maintaining these lepers.

The Bureau of Health has recently completed another leper-collecting trip which included all provinces of the Philippines, and as a result, 293 lepers were transferred to the Culion leper colony. So far as known, all cases in the Philippines have now been isolated. There has been a very marked change in sentiment with regard to isolation, and many persons afflicted with the disease present themselves voluntarily.

During November there was a sharp increase in the number of diphtheria cases encountered in the city of Manila, and many bacilli carriers were found. These were invariably isolated at the San Lazaro Hospital, which action evoked spirited protests from the public against the isolation of persons apparently in good health. The prompt subsidence of the disease, however, has apparently fully justified the course which was taken.

Dr. R. P. Strong, for so many years the Chief of the Biological Laboratory of the Bureau of Science, has tendered his resignation.

Dr. Zack Laughlin, Medical Inspector, Bureau of Health, has returned from an extended leave of absence in the United States, and has been reassigned to his former district of Ambos Camarines and Albay.

## Progress of Medical Science

5. On the Nature of the Feeling of Unreality. J. W. Courtney.
6. A Report of Two Cases of Tuberculous Mesenteric Glands of the Cecal Region. C. G. Cumston.

1. Functions of the Free Dispensary.—W. S. Thayer agrees with Richard Cabot that the out-patient department is the most important part of a hospital. It reaches most directly the general public in its function of giving advice and offering care to the sick as well as in its larger function of instructing in methods of life and prophylaxis against disease. It is the one part of a hospital in which students of medicine are able to study these diseases with which they are most likely to meet in general practice. The dispensary should be an institution so equipped and conducted as to be a central point to which the physician practising among the poor should be able to resort for consultation and advice with regard to difficult and complicated cases. The abuses to which dispensaries are subjected are trivial. The chief dispensary abuses are the abuse of patients by careless doctors and externes and the abuse of opportunities by careless doctors and externes. In any dispensary constant care is needed as to the personnel of the staff and as to the character of the

work done. Especially important is the establishment of a social service department.

3. **Diphtheria in Institutions.**—H. M. Adler states that a patient suffering with indefinite catatonic symptoms should be carefully examined for physical disease, even if the usual signs of acute disease, such as fever, pain, etc., are lacking. A diphtheria bacillus may be causing active disturbance without local manifestations. A true diphtheria bacillus may be introduced into the wards of an institution for the insane and spread without causing clinical diphtheria among the patients. The diphtheria bacillus under these conditions maintains its virulence and is capable of causing clinical diphtheria. The diphtheria bacillus does not as a rule cause typical clinical diphtheria in insane patients. The attendants are liable to infection with true diphtheria, and often present the clinical picture of diphtheria, although none of the patients in their charge are characteristically ill with the disease. Diphtheria antitoxin should be freely used even in the absence of clinical diphtheria.

5. **The Feeling of Unreality.**—J. W. Courtney infers in the case of the victim of unreality that the visual impressions are so lacking in vividness that they do not carry into consciousness anything beyond the presenting flat surface of the solid object seen. In other words, a diffusion of the visual stimuli does not take place; presentation and representation in consciousness of these stimuli are lacking. Without this diffusion complete normal perception is impossible. To what, asks the author, may one attribute this lack of vividness and coherency of relation in the primary sensational elements, which leads to the feeling of unreality? Its explanation is simple if one bears in mind that the feeling in question is never a clinical entity, but for the most part constitutes merely a single symptom of that very complex adynamic state of the entire nervous system, which is termed psychasthenia. In this last named disorder there is, as every clinician knows, a marked lack of tone in all the bodily functions. Physical exertion produces prompt over-fatigue; the blood-pressure is below normal; the secretions of the digestive glands are inadequate; in a word, the whole picture is one of adynamia. And into it, on this basis, the feeling of unreality best fits.

8. Medical Inspection of Schools. J. F. Edwards.
9. Chronic Ulcers of the Leg. W. Brady.
10. Gastric Symptoms in Incipient Tuberculosis. M. M. Jacobs.

1. **Fats and Carbohydrates in Nutrition.**—By H. D. Chapin. (See MEDICAL RECORD, February 15, 1913, page 316.)

2. **Scoliosis and School Seating.**—J. W. Sever notes that school desks should leave room enough for the knees, and should be low enough so that the elbow and forearm may rest comfortably on them without bending the back. The slope of the desk theoretically should be about 30°; but as that is too steep an angle to allow books and papers to rest on it without sliding off, a compromise angle of from 12° to 15° has been selected. The seat should be no wider than the width of the hip, for wider seats predispose to slouchy attitudes. It should be about two-thirds the length of the thigh. It may or may not slope very slightly backward, but this is of no great importance. Any great slope is distinctly bad. The height from the floor should be such as to allow the feet to rest equally and comfortably on the floor. A seat of too great breadth, as well as one of too great depth, compels bad postures. The seat should have a back which supports the lumbar spine when sitting, at work, as well as at rest.

4. **Physical Therapeutics.**—By W. B. Snow. (See MEDICAL RECORD, Vol. 82, page 1071.)

5. **High Frequency Currents.**—By F. de Kraft. (See MEDICAL RECORD, Vol. 82, page 1011.)

9. **Treatment of Chronic Leg Ulcers.**—W. Brady outlines this treatment as follows: Cleanse the ulcer with warm normal salt solution, dry carefully with wisps of cotton, and dust on a light application of an anesthetic antiseptic powder; then apply a sterile petrolatum gauze pad and a light packing of cotton and bandage from toes to knees. This will invariably give great relief from pain and inspire the patient"s confidence. If inflammation or eczematous erythema is pronounced in the skin about the ulcer, a large wet dressing is required, with perfect rest for a few days. This dressing had better be normal saline solution for the first few times, kept wet by pouring fresh warm solution through a window flap in the oiled silk over the gauze. Should one find the ulcer covered with an old slough, brewer's yeast, if obtainable fresh, every two or three days makes an excellent dressing. It must be changed twice a day, covered with oiled silk or other impervious protective, and applied warm, without antiseptic contamination. Yeast must be kept cold. In old, dry, scaly ulcers with little or no secretion, the suggestion of Wright should be followed: Apply a wet dressing of one-tenth of one per cent. of citric acid and four per cent. sodium chloride solution, and administer citric acid in dram doses every three or four hours for a day or two. This will start a serous drainage from the ulcer and institute the processes of repair. For exuberant granulations there is but one cleanly remedy, the scissors. Pressure applied by means of adhesive straps, gauze pads, and proper bandaging will take care of moderately high granulations. In varicose ulcers a very effective procedure is elevation of the limb. Once the granulations assume something like a healthy, smooth, glistening, moist surface, at or near the level of the surrounding skin, the less one does the better. A simple sterile petrolatum dressing, merely to keep the gauze from sticking to the wound, is all that is ordinarily required. When the granulating surface contracts to an ulcer the size of a dollar, a neutral powder—sterile talcum, for instance—freely applied to the carefully cleansed and dried ulcer, covered with a few layers of gauze, and strapped in place with adhesive strips, is the best management. This should not be disturbed oftener than every fourth or fifth day—or even less frequently if there is no trouble from serous discharge.

10. **Gastric Symptoms in Incipient Tuberculosis.**—M. M. Jacob concludes that pulmonary tuberculosis in its incipient form may present gastric symptoms similar to typical organic or inorganic stomach lesions. Gastric disorders may be considered as among the first symptoms of pulmonary tuberculosis. Hyperacidity or normal acidity is the rule in incipient tuberculosis. The secretion of hydrochloric acid is independent of fever.

**4. The Skin-Grafting Operation for Cancer of the Breast.**—W. S. Halsted describes his latest technique as follows: The incision down the arm, made shorter and shorter, was finally abandoned. The vertical cut to the clavicle is made as short as feasible and when considerable skin has been removed above is omitted. Not infrequently the only incision of the skin is the circular one surrounding the tumor, but as a rule the one or the other of the vertical incisions has been made. By means of the two vertical incisions, one above and one below, the dissection of the axilla is, of course, facilitated. Thus the triangular flap has been definitely abolished. The skin of the outer flap between the two vertical incisions is utilized primarily to cover completely, without any tension whatever, and redundantly the vessels of the axilla. The edge of this flap is stitched by interrupted, buried sutures of very fine silk to the fascia just below the first rib in such way that the skin partly envelops the large vessels. Then, along the entire circumference of the wound, the free edge of the skin is sutured to the underlying structures of the chest wall, the wound being made as small as desirable in the process of closure, and tension on the upper or axillary part of the outer flap assiduously avoided. Considerable traction may, however, be exercised on the mesial flap and on the lower portion of the outer flap. Whatever the size and shape of the grafted defect, it should usually extend to the top of the axillary fornix. Thus the thoracic or inner wall of the apex of the axilla is always lined with skin-grafts. The advantages of skin-grafts are given by the author practically as follows: An almost unlimited amount of skin may be removed, and from his experience the results have been better the larger the areas of skin taken away, and the wider berth given the tumor. Skin-grafts present a definite obstacle to the spreading of cancer metastasis, as the growth does not tend as much to invade the grafted area. In some cases when there is a special tendency to dissemination in the skin, which he formerly regarded as hopeless, it occurred to the author that by surrounding the denuded and grafted area, more or less completely, according to the case, with a kind of moat this tendency to spread might be confined to the intervening region between the two grafted areas, the operation wound and the grafted area. The moat is formed by the excision of a narrow strip of the skin with its underlying fat and loose tissues. Possibly the gap made by the mere incision through the skin to the sheaths of the underlying muscles might sometimes be sufficient. If the moat is made at the primary operation the grafts on it should be covered with silver foil, which is an admirable dressing for uninfected surfaces when it is desired to leave them undisturbed for a week or more, as in breast cancer operation. For infected or granulating surfaces some other permeable and non-adhesive dressing like rubber should be used. If the grafting of the moat is delayed the Reverdin grafts are preferable to the Thiersch grafts. Recurrence in the deeper planes can be promptly detected under the thin grafted skin and should be burnt away, down to the pleura if necessary, by the actual cautery. Halsted disapproves of the suggestion of covering the defect by transferring the opposite breast, as it would conceal any deep recurrences. The inner or thoracic wall of the axilla being covered to the apex of the axilla by grafts, the skin of the outer flap can be used, in redundant fashion, for covering the axillary vessels, for obliterating the subclavian dead space, and for elevating the axillary fornix.

**5. Ulcer of the Bladder.**—L. Buerger states that while solitary ulcer of the bladder is considered very rare, two cases have recently come under his observation, which he reports. The condition may be frequently overlooked. Both cases had been examined with the cystoscope, but the cause of the most striking symptom, hematuria, had not been discovered. From the location of the ulcer, on the posterior vesical wall, the region often poorly shown in routine inspection, the ulcer is liable to be missed. The author specially refers to the work of Le Fur and Siredey as the most comprehensive contribution on the subject and summarizes the conclusions that may be deduced from the rather meager observations as follows: A careful search should be made in all cases of vesical hematuria for the presence of a simple solitary ulcer. Bleeding ulcers may be overlooked if one fails to bring every portion of the superior and posterior walls of the bladder in view. The most striking symptom in the cases under observation was hematuria, persisting for more than two years in one of the patients. In the treatment of this condition, as well as in the treatment of tuberculous ulcer after nephrectomy, the fulguration method should be tried, and if this fails mercurial injections should be given in cases of simple ulcer. Future studies should be directed toward the investigation of the etiology of this affection both by careful consideration of the histories of the cases and by thorough bacteriological examinations.

**6. The Position of the Stomach and Gastroptosis.**—R. F. Chase believes that there should be a change in present views as to gastroptosis and its relations to digestive disturbances, neurasthenia, etc. From his examinations and other data he finds that in the horizontal position the greater curvature of the stomach is found a little above the umbilicus in the average individual, though the normal limits range from two and one-half inches above to one inch below. In the vertical position the *x*-ray shows it to be considerably lower. By any reliable determination it would seem that in diagnosing gastroptosis one must find the greater curvature at least one inch below the umbilicus. The generally accepted views must therefore be modified and gastroptosis be less frequently diagnosed. Instead of considering it as present in 33 per cent. of females one will have to reckon on the percentage at somewhere about 10 per cent. The observed infrequency of digestive disturbances in alleged gastroptosis is thus easily accounted for. Fenwick estimates that gastroptosis may be the cause of indigestion in about 5 per cent. of cases. The author also appears to question its importance as a cause of stasis. Even in marked cases of gastroptosis the stomach sometimes empties itself prematurely, notwithstanding the "duodenal hill" over which its contents must be forced. The radiograph will teach more rational treatment and do away with much needless surgery. Far less attention will be paid to the position of the stomach as a cause of symptoms elsewhere as long as it is known to be properly doing its own work.

**12. Blood Transfusion.**—T. B. Cooley and J. W. Vaughan remark that, while the Crile method of direct transfusion is not difficult for one with special training and practice, others may experience difficulties with it that render it almost impracticable. For this reason they describe a case which they report because of the successful method employed. The patient was a baby two days old, who was suffering from severe hemorrhages from the stomach and bowels, until it had become nearly exsanguinated. Horse-serum failed to check the hemorrhage and Crile's method was attempted. Owing to the smallness of the collapsed veins of the child, who by this time was cold and pulseless, immediate action was imperative, so they concluded to try taking the blood from the vein of one of themselves into a glass syringe and injecting it into the child's veins before clotting could begin. The blood was drawn from the basilic vein of the donor into a glass syringe into which 1 c.c. of physiological salt solu-

tion had been previously drawn. It was filled to nearly its full capacity of 10 c.c., the sharp needle was changed for a blunt one and the blood was injected rapidly into the child's vein. This was followed immediately by one of salt solution. Improvement appeared within 15 minutes in the previously imperceptible pulse, and 10 c.c. more were injected. From this time on the recovery was rapid and uneventful and the child was saved. The total amount of fluid, blood, and salt solution injected was not accurately measured, but was probably between 20 and 50 c.c. The father's serum had been injected prior to the transfusion and there were no further hemorrhages. Although the authors say that many bloods will coagulate within three to three and one-half minutes, this affords ample time to carry out transfusion in the way described. Of course, it is essential to work rapidly.

15. **The Albumin Reaction in the Sputum of Tuberculous Patients.**— J. R. Scott concludes that in cases which have been clinically diagnosed as pulmonary tuberculosis, in which also the examination for the tubercle bacilli has been positive, there is an absolutely negative albumin reaction in about 10 per cent. The positive albumin reaction is admittedly of little value, since it may occur in any of a number of different diseases of the respiratory tract. The value of an "inconsiderable" or doubtful reaction is questionable. Practically all the albumin reactions are of no value in the routine diagnosis of pulmonary tuberculosis: (a) because the positive reaction occurs in many affections of the pulmonary tract other than tuberculosis; (b) because a negative reaction may occur in about 10 per cent. of positive pulmonary tuberculosis cases; (c) because with the test there are certain variations which would have to be eliminated in each sputum examined to permit of a reliable result; and (d) because in the case of an "inconsiderable" or "doubtful" reaction, one does not know in any given case how much importance to attach to the reaction.

2. **Salvarsan in Syphilis.**—L. Kilroy reports his results as follows: Of 2,147 injections which were given to 1,000 cases there were 13 invalidings, no deaths, and 22 clinical relapses re-admitted to the author's hospital, 2 clinical relapses admitted to other naval hospitals, and 2 occurring in ships. Leaving out of consideration the salvarsan given after relapses, of 17 patients (5 of whom had previously received salvarsan elsewhere) who received one dose of salvarsan, no case reached the hospital as a clinical relapse. Of 901 cases receiving two injections, 21 cases reached the hospital as relapses, 2 are known to have occurred in ships, and 2 have been treated in other naval hospitals. Of 68 cases receiving three injections, one case reached the hospital as a clinical relapse. Of 14 cases receiving four injections, no case reached the hospital as a clinical relapse. One case of relapse after two doses given elsewhere has been treated by two further doses.

3. **Late Suppurative Posttyphoid Osteitis.**—A. H. Tubby and J. A. Braxton Hicks report the case of a man who thirteen years after an attack of typhoid fever developed a suppurative osteitis of the ulna. During the man's stay in the hospital several interesting clinicopathological investigations were carried out. A leucocyte count, taken on admission, showed no leucocytosis, and a Widal reaction with the patient's serum and three different strains of *Bacillus typhosus* was negative in a 1 in 20 dilution of the patient's serum after one hour, though controls readily agglutinated in a 1 in 200 dilution. Agglutination reactions with the paratyphoid group were also negative. The pus from the wound contained in pure culture a bacillus giving all the cultural reactions of *B. typhosus*, and this bacillus was also agglutinated by a known typho-agglutinating serum and fixed complement in the presence of a "typhoimmune" serum. *B. typhosus* rapidly disappeared from the discharge from the wound and could not be found a week after the operation. The urine and feces were examined for the presence of *B. typhosus* with negative results. The patient's serum would not agglutinate this bacillus obtained from the wound, but emulsions of the bacillus and other strains of *B. typhosus* were able to fix complement in the presence of the patient's serum. Complement fixation experiments with the other bacteria and the patient's serum gave negative results. This property of the patient's serum to "fix complement" but not "agglutinate" in the presence of its "own" *B. typhosus* or of foreign strains is regarded as an extremely interesting one. Following operation the patient made an uneventful recovery.

4. **Progeria and Ateleiosis.**—By A. Keith. (See page 345.)

5. **New Growth and Inefficient Immunity.**—H. G. and A. S. F. Grünbaum have observed that after the injection of streptococcus vaccine into the rat, during a period roughly corresponding to the negative phase, there is present in the rat's serum a substance which accelerates cobra venom hemolysis and later on disappears. In sarcomatous rats the following conditions are present: (1) A persistent hemolytic property of the serum. (2) An absence of, and usually an inability to produce, antitoxin to cobra venom; if its production can be excited, the tumor regresses. (3) The administration of antitoxin in the form of antivenom serum causes regression of the tumors. It seems, therefore, reasonable to infer that the absence of some immune body and the present of a hemolytic substance in the serum are factors which exert an influence on the growth of the tumor. Injection of vaccines in man also leads to the appearance of a hemolysophilic property in the blood. The administration of certain immune bodies will cure sarcoma in rats and will diminish new growth in man. The authors report a case of round-cell sarcoma, which steadily improved during the administration of artificial immune substance in the form of antivenom serum but never showed any response by antibody production to cobra venom toxin. The body weight steadily increased and the tumor mass decreased markedly in size. Another case, one of carcinoma of the larynx, likewise showed no reaction to injected toxin, but put on 14 pounds in weight, and improved steadily so long as the artificial immune body (in this case diphtheria antitoxin) was administered (eight weeks).

9. A Case of Cardiac Asthma. C. Wilson.

1. **Bacteria in Relation to Uterine Fibroids and Cancer.**—Sir John Bland Sutton states that it is undeniable that death from pulmonary embolism is especially frequent after abdominal hysterectomy performed for cancer of the uterus; it is far more frequent than after the removal of the uterus for fibroids, and the evidence indicates that the greater frequency of this catastrophe in operations for cancer of the uterus depends on the greater luxuriance of the flora in cancerous tissue, and that the streptococcus, of all the forms of microorganisms which abound in such uteri, holds the greatest "enmity with blood of man." In order to improve the results of abdominal hysterectomy performed for fibroids, surgeons must be more careful and more moderate in the use of buried sutures when closing the abdominal incision. The risks of operations for cancer of the neck of the uterus will be lessened when surgeons, with the aid of bacteriologists, devise means to rid cancerous tissues of noxious organisms before undertaking hysterectomy. The widespread tilling of the pelvic connective tissue inseparable from the operation ironically called radical abdominal hysterectomy favors the sowing, growth, and rapid multiplication of streptococci, with the result that in many instances death results.

2. **Atypical Exophthalmic Goiter.**—H. L. McKisack refers to cases of this disease in which the majority of the classical signs are absent. These cases are apt to be overlooked. They are too few to permit any reliable generalizations to be founded on them; but it is noted that in all the heart-rate is above normal, and in practically all the patient is aware of the rapid beating, either in the form of general throbbing of the arteries or as palpitation of the heart. This is the symptom which should always arouse suspicion, and when combined with tremor and with even a slight protrusion of the eyeballs it may be accepted as an evidence of hyperthyroidism. This last-named sign was, however, absent in fifteen of the author's twenty-one cases. Careful examination generally reveals an increase in the size of the thyroid—sometimes only to a very slight degree. In three cases it was normal, in five it was of moderate size, in two considerable enlargement existed, and in eleven there was slight enlargement. Tremor was absent in nine of the cases. Twelve of the cases were between the ages of puberty and thirty, and the remainder were between thirty and sixty. All but three were females, and one of the three men, while incomplete in the development of signs when first seen, soon progressed rapidly in an unfavorable course, and became a typical case in a very short time. Two of the cases showed marked vasomotor excitability. As regards the treatment of these atypical cases, it differs in no material respect from that of the fully developed disease. The author advocates a trial of the *x*-ray treatment. This procedure seems to offer a fair prospect of reducing the activity of the gland, without having to subject the patient to the risk of an operation for the purpose of removing a portion of the gland or ligaturing some of its vessels. Finally, the author suggests that the name "exophthalmic goiter" be as far as possible discarded, and that the condition be spoken and thought of as "hyperthyroidism." This term would include all degrees of the abnormal condition, while the more usual description, "exophthalmic goiter," merely suggests two of the chief, but by no means the most constant, symptoms.

3. **Portals of Entry of the Tubercle Bacillus.**—E. Emrys-Roberts states that there exist portals of entry of the tubercle bacillus that have long been recognized. For example, no one denies the transmission into the lungs of tubercle bacilli suspended in air in minute particles of moisture or in dust. Recent experimental evidence has amply demonstrated this very important avenue of infection, and has incidentally shown that the number of bacilli required, all things being equal, to set up pulmonary tuberculosis is relatively small as compared with the number necessary to induce tuberculosis elsewhere—as, for example, into the intestinal tract. No one questions transmission through the intestinal tract, especially in infancy, and here, again, experimental evidence shows that not only may the bacillus induce a lesion in the gut, but may enter the intestinal wall without producing a lesion at the seat of entry. No one, again, questions transmission through the nasopharynx; there is ample evidence, both clinical and experimental. Transmission can occur also through the skin. Experimentally, transmission through the unbroken skin has been demonstrated. Lastly, one reaches the antenatal avenue of entry. Omitting for the present this last portal of entry, one may say, with Calmette, that "the more frequent channels of invasion are the mucous membranes of the natural cavities of the body, particularly the digestive and pulmonary epithelium, and to these may be added the naso-pharynx." Whether one can go further with him and say, "Of these the digestive path is the one most commonly chosen," is, according to the author, open to question.

4. **Tuberculin in Tuberculosis.**—N. Raw concludes on the basis of the treatment of over 600 patients with injections of tuberculin that this is a remedy of the greatest value, especially in early cases and where the deposit of tubercle is localized, as in one apex or in a lymph gland or single joint; but where the tuberculosis is disseminated and complicated by secondary infection the use of tuberculin cannot be expected to be of much avail. It ought, however, to be tried in every case with the hope of some relief or possible benefit, as we cannot allow the patient to suffer and die without making every effort to arrest the progress of the disease. Tuberculin is not going to revolutionize the treatment of tuberculosis. It is a valuable aid to the other methods of treatment, hence it must be used with care and discrimination and with a full knowledge of its dosage and therapeutic effects. The best treatment one can offer to-day to a person infected with tuberculosis is a prolonged open-air life, preferably in a well-conducted sanatorium, excess of nutritious food, gentle exercise followed by plenty of rest, and a course of tuberculin by a careful physician.

---

**Studies in Animal Tumors.**—Lewin sums up a long article by stating that the chemotherapeutic method of Wassermann, Neuberg and Caspari may indeed fail in individual cases but is plainly seen to exert a uniform specific activity. The cell poisons which are employed we know to be tumoraffin, but we do not know in just what manner, they influence the cells to their disadvantage. The necrotic change may be due to direct action on the cells or may be effected through the blood vessels. The subject cannot of course be verified upon human tissues. Hence the author prefers to work along strictly biological lines, such as are being tested extensively in other diseases. Tumor substance, tumor autolysates and similar products can be made to antagonize the growth of tumor cells. These substances circulate in the blood and there is no reason for a belief that they can poison the cancer cells in any but the most direct fashion. Unlike some of the metals and other extraneous bodies used they behave inertly to the organism at large. Clinical results have long ago been claimed for serotherapy in malignant diseases—by Coley's fluid, antimeristem, Doyen's serum, etc.—just as they have for chemotherapy (arsenic, silica, etc.). Of the two procedures biological therapy and chemotherapy, the author believes the former to be far better grounded in reason, and that work along this line will be much more profitable than chemotherapy in the long run. —*Berliner klinische Wochenschrift.*

## Insurance Medicine.

### FAITH CURE AND INSURANCE.

To the Insurance Editor:

Sir:—Do insurance societies make provisions for conditions of this kind, which in these days of irrational creeds are by no means uncommon? A short time ago I was called in to give a diagnosis as to whether a patient, who had been sick for four and a half weeks, had enteric fever. Clinical symptoms, Widal, and blood count established a positive diagnosis. I found the relatives Christian Scientists. They would of course accept no advice as to vaccines or medicinal treatment, and I left them with the usual suggestions as regards diet and prevention of infection. Two weeks afterwards I was applied to for a death certificate. Two weeks ago I was applied to under the following circumstances: A man had refused to have any medical advice for his wife who was said to be suffering from pulmonary tuberculosis. The wife apparently agreed with her husband. I was asked if I did not know of some law which would cover this. Beyond the restrictions imposed on such cases by the Health Office I know of none. The latter case is possibly not so serious as the former. If, however, people are through prejudice to let their patients die, when rational treatment would certainly save some of them, it seems to me the insurance societies have a problem on their hands, of increased risks, in these cases.

Francis Mead, M.D.

San Diego, Cal.

[The principles of life insurance are based upon standard mortality tables which were compiled by some of the world's greatest actuaries after studying the experience with hundreds of thousands of insured lives. These lives had been selected after the elimination of all kinds of debatable risks, and they represented individuals who had been strictly orthodox in their views as to the importance of medical aid. The great army of policyholders now living have contracted for life insurance with the understanding that the companies will continue to select risks on conservative and scientific principles and that they will not deviate from or change any of these principles unless they can secure sufficient data to justify them in such a step. The officers of the companies, who are merely custodians of the money of these same policyholders, would be recreant to their trust if they were to violate this understanding.

The daily press furnishes statements from time to time which would indicate that followers of some creed or other have died after refusing medical aid which would have probably saved their lives. The surviving believers in these doctrines or articles of faith will doubtless contend that the statements are not accurate. It is far from our desire or intention to enter into the discussion of the merits of either side in such a controversy. The fact remains, in any event, that there is grave doubt in the minds of nearly all policyholders, the virtual owners of the companies, as to the complete efficacy of any form of faith cure in the treatment of illness or accident, and that they could, therefore, criticise their respective companies for insuring those who, according to their own statements, would refuse medical aid in the event of illness or accident. The companies will not be in a position to assume such risks until they possess reliable statistics which are free from prejudice, uninfluenced by faith or sentiment, and based on a sufficiently wide experience to convince impassionate officers and actuaries that the risks in question can be carried without injury to the interests of the other policyholders.—Editor.]

**The Wassermann Reaction and Its Value in the Detection of Syphilis.**—Dr. Amand Ravold defines the Wassermann reaction as a highly complicated chemicophysiological reaction, the rationale of which is unknown, but which depends upon the physicochemical interaction between substances produced by the growth of the *Treponema pallidum* in the body, and found resident in the globulin fraction, and lipoids of the antigen. The reaction is not specific, but the experience with many thousand reactions performed throughout the world has shown that when properly performed and under certain limitations it is of inestimable value in the diagnosis of syphilis. Every time the test is made the reagents used must be freshly prepared and tested and carefully standardized; this work takes a careful serologist at least five hours. Ravold tells of ninety-eight carefully followed cases to show the value of the reaction. The number of primary lesions among these was forty-two, and Wassermann was positive in three, or 7 per cent. The clinical diagnosis was correct in forty, or 95.3 per cent. The clinical diagnosis was wrong and the Wassermann was negative in two cases. In the early secondary stage there were twenty-one cases, and Wassermann was positive in all but two of these. All had clear histories and typical primary and secondary lesions so that Wassermann was of no other but corroborative value. There were five tertiary cases, all diagnosed clinically, even though Wassermann was negative in three of the cases. In the latent and late stages the Wassermann reaction was positive in a surprisingly large number, 63 and 60 per cent., and when positive was of decided value as confirmatory evidence.

The serum acquires the property of giving rise to the reaction when the spirochetes have passed from the lymph into the blood stream late in the primary stage. The reaction is therefore of little value early in the disease except in cases of extragenital chancres, because the diagnosis can be made and treatment instituted long before the reaction becomes positive. In the secondary cases it is of little value except in atypical eruptions, where a negative reaction several times repeated is of decided value. In the tertiary stage it is of decided value when positive two or three times but it fails to be positive in a large number of cases. A negative reaction in this stage is therefore of no value unless it is repeatedly found.

The reaction is not specific because it has been obtained in protozoal diseases such as trypanosomiasis, in frambœsia, in tuberculous leprosy, malarial fever, some cases of scarlet fever, after treatment with antirabic vaccination, late in some cases of tuberculosis, etc. Ravold thinks that because of the work of inexperienced men the diagnosis of syphilis has been fastened upon a number of persons not ill of the disease, a positive Wassermann reaction being looked upon as surely pathognomonic of the disease. He thinks that the reaction is now generally condemned, and does not approve of this second extreme any more than of the unbounded enthusiasm first noted. Most important of all is a good serologist to perform the test, and the physician should lay aside all sentimentality and prejudice in selecting one to do his work. He should

make sure whether the man does his own work or relegates an important part of it to the office girl or a half-grown assistant. Then his work should be tested by sending him blood from patients manifestly syphilitic or surely free from the disease. The patient should never be sent to the serologist but the blood should be taken by the physician and sent to the laboratory. Ravold describes in detail the method of obtaining blood and warns against a needle with a dull point which simply pushes the vein away without piercing it. He has found that a large hypodermic needle is sufficient to obtain the amount of blood necessary for the test. The specimen should always be divided into two parts and sent to two different serologists or a portion sent to a friend who can send it to the same serologist. The tubes should be differently marked and care should be taken that the serologist should not find out that they are from the same person. Positive results from two different men become of decided value when all these precautions are taken. Often enough they do not agree and the error must then be searched for. Negative reactions are of value only if repeated several times. The laboratory man should not be looked upon as a consultant but as an assistant and his work should be scrutinized with the greatest care.

The Wassermann reaction should be looked upon as a symptom and should take its place in the symptomatology of syphilis. It is not the whole disease, it is not the court of last resort, and it is not infallible. The limitations of the reaction are many and the limitations of the worker with it boundless. In this country, however, the reaction is of greater value because of the extreme rarity of some of the diseases other than syphilis in which it may be present. The reaction has no prognostic value. A continuous reaction indicates in the great majority of cases that the patient is still actively syphilitic and needs further treatment, but a negative reaction does not mean the cessation of treatment. Persistent negative reactions determined several months apart may mean not that the patient is cured but that an equilibrium has become established between the germ and his body, the spirochete having become a saprophyte. There is ample proof, however, that syphilitics are cured of the disease, the best evidence being the number of reinfections reported. In the great majority of cases syphilitics, although apparently well and presenting no active symptoms of disease, are still uncured.

From the life insurance standpoint it is manifestly impossible to require a Wassermann reaction from an applicant who does not acknowledge syphilis. Very few applicants ever admit having had the disease and those that do, but have no active manifestations of the disease, believe themselves to be cured. If a Wassermann reaction is taken and proves negative the applicant would be insurable on a plan in accordance with the views on syphilis of the particular medical director. If positive the applicant would be ineligible and remain so until it had become persistently negative after treatment. Who is to pay for the reaction? Certainly not the company; but if the reaction is positive and the applicant is not admitted, he may only learn what he knows already. Once it becomes known that an acknowledgment of syphilis means added expense in getting insured no applicant will admit a previous infection. Ravold concludes that the Wassermann reaction is of no value to the medical director.

In the discussion that followed Dr. Harris said that the reaction should be tried with several antigens and the serum of the patient should be titrated, for then very weak reactions would not escape notice. He thought that in the secondary stage the reaction is positive in almost all cases and it is more frequent in late stages than is believed by Dr. Ravold. The reaction is of value in life insurance in diagnosing latent secondary and tertiary stages. The reaction may not be constant in such cases but it frequently is the only symptom and should be valued accordingly. The reaction in general is only a symptom of syphilis, but it is the most constant symptom and the longest persistent symptom. These two characteristics make the reaction of great significance both clinically and from the life insurance standpoint. Dr. Harris thought that the expense of having the test made should be borne by the applicant.—Second Annual Meeting of the Medical Section of the American Life Convention.

**Accident and Injury in Relation to Pulmonary Tuberculosis.**—J. B. Hawes, 2d, and A. Drinkwater note that cases of tuberculosis following chest injuries are not uncommon. In such cases the train of events is usually so clear as to leave no doubt as to the part played by the injury as the direct or proximate cause of the subsequent tuberculosis. So far as the question of recovery of legal damages is concerned, it is immaterial whether the injury has led to a definite infection with tuberculosis or has awakened an old latent process. Thiem reports the case of a mason who fell and fractured his skull. On examination at this time his lungs were found to be normal. He recovered from the injury, but during convalescence developed a pleurisy which turned out to be tuberculous. The same author reports the case of another man who was struck in the side by a heavy box. Six months later he had a hemorrhage and developed consumption. Recently the Supreme Court of Minnesota gave damages for the death of a man from pulmonary tuberculosis who had suffered a severe accident eight months prior to his death. He was then 43 years old, in perfect health according to a good medical evidence, weighed 188 pounds and was a big, robust man. He received a severe head injury with considerable shock and concussion, as a result of which he was confined to the hospital for one month. He continued to lose steadily in health and strength and soon developed consumption, from which he died eight months later. The defense argued that pulmonary tuberculosis often attacks men of robust health and kills them. The Court, however, believed that the evidence was sufficient to sustain a finding that the injuries suffered were the proximate cause of this man's death; he further stated that, although these questions are often obscured by technical learning, they are usually questions of fact for the jury, to be solved by the exercise of good common sense in the consideration of the evidence in each particular case. Chief Justice Knowlton states the difficulty in these cases thus: "The question is often difficult to decide whether an unusual condition is the active, efficient and proximate cause of a subsequent event, or is only a producer of conditions which open the door to another cause which directly and actively produces the result." No definite ruling can be laid down according to which these cases can be decided. They are bound to occur more and more frequently, as the public gains knowledge in regard to this disease.—*Boston Medical and Surgical Journal*, January 16, 1913.

# Book Reviews.

Les Produits Biologiques Medicinaux. By P. Byla et R. Delaunay. Price 10 francs. Paris: Société D'Éditions Scientifiques et Médicales, 1912.

This book is published by the manufacturers of biological products, Messeurs Byla and Delaunay. The book gives information as regards the method of preparing the different gland extracts, as well as their therapeutic uses.

The Business of Mining. A Brief Non-Technical Exposition of the Principles Involved in the Profitable Operation of Mines. By Arthur J. Hoskin, M.E., Consulting and General Mining Engineer; Western Editor "Mines and Minerals." Formerly Professor of Mining, Colorado School of Mines; Member, American Institute of Mining Engineers; Member, Colorado Scientific Society. With 16 Full Page Illustrations and one Chart. Price $1.50. Philadelphia and London: J. H. Lippincott and Company, 1912.

This monograph on mining dealing with the subject from the historical, scientific and above all from the business point of view is timely. As the author points out, a large number of persons speculate in mines with no knowledge of the matter whatever and the book has been written with the view of explaining mining mainly from the business aspect. This is a laudable endeavor and doubtless Mr. Hoskins has provided some extremely valuable information, but whether the speculating, or even the investing, public will profit from the facts set down so clearly in this book is another question altogether.

Preventable Cancer. A Statistical Research. By Rollo Russell. Price $1.50. London, New York, Bombay and Calcutta: Longmans, Green and Co., 1912.

The author of this book presents some general evidence that cancer is most prevalent among people who live on a rich diet with meat and eat their food while it is hot. He also believes that alcohol, tobacco, tea, and coffee are etiological factors. Authorities for the evidence that the clay pipe, soot, the Kangri, coal tar, and arsenic may cause cancer are cited.

The book is not a scientific work; where valuable evidence might have been collected, as, for instance, in regard to the prevalence of cancer among the Doukhobors the author has relied upon general reports. As to one of his sources of information in this country the author is evidently ignorant of the large proprietary interests that were really speaking.

An Essay on Hasheesh. Including Observations and Experiments. By Victor Robinson. Contributing Editor Medical Review of Reviews; Pharmaceutical Chemist, Columbia University; Member of the American Chemical Society; Author of "Pathfinders in Medicine." Price 50 cents. New York: Medical Review of Reviews, 1912.

This work shows great promise from the literary standpoint. It is written in glowing language quite in keeping with the subject and the Far East. From the scientific point of view it is of no particular value, although the history, chemistry, and therapeutical merits of the drug are well described. It is an interesting volume and gives rise to the hope that Mr. Robinson in the future may do good and enduring literary work.

The Principles of Hygiene. A Practical Manual for Students, Physicians, and Health-Officers. By D. H. Bergey, A.M., M.D. First Assistant, Laboratory of Hygiene, and Assistant Professor of Bacteriology, University of Pennsylvania. Illustrated. Fourth Edition. Thoroughly Revised. Price $3.00. Philadelphia and London W. B. Saunders Company, 1912.

At the present day Hygiene is one of the most important branches of medical science, in that it aims at preventing disease instead of curing it. The book under review is, so far as it goes, one of the best of the smaller works on the subject, and for the medical student and practising physician it will prove very satisfactory. In spite of the title-page, we think that health officers will require one or more works which deal with the various branches of the subject in a much more exhaustive manner. The volume contains chapters on: Air, ventilation, heating, water, and water-supply, removal and disposal of sewage, garbage disposal, food and dieting, exercise, clothing, personal hygiene, industrial hygiene, school hygiene, military hygiene, naval hygiene, soil, habitations, vital causes of disease, disinfection, quarantine, and vital statistics. The information given is well selected and well arranged; and the book has been written by one who is acquainted with the conditions which prevail and appliances which are found in this country. Many manuals of hygiene, good in themselves, lose much of their value because they describe conditions and apparatus which are foreign, and often unknown to the reader; the present work is a notable exception.

Principles of Human Physiology. By Ernest H. Starling, M.D. (Lond.), F.R.C.P., F.R.S., Hon. M.D. (Breslau); Jodrell Professor of Physiology in University College, London. Price $5.00. Philadelphia and New York: Lea & Febiger, 1912.

The extensive and complex developments of modern medicine require of the student to-day, more than of the student of a decade ago, a comprehensive knowledge of physiology. The pivot of medical studies is found in the elucidation of morbid changes in function to a greater extent than in the mere recognition of pathological changes. Physiology in turn has sought to broaden its foundations and has drawn freely upon the auxiliary sciences of physics and chemistry. The complete textbook of physiology must therefore interpret for the student the important bearings of organic chemistry and of physical science so far as they relate to biological phenomena. In the present volume the author has surveyed the entire domain of modern physiology and has indicated its relation to the frontier subjects of physics, chemistry, and clinical medicine. Within one volume of 1423 pages he has included without the sacrifice of necessary detail and of clearness practically all that is known about physiology at the present day. The philosophical conceptions that lie at the root of this science are not neglected. The deep insight by the author and his facility of expression are perceived in the following statement: "We have no reason for asserting that, in the course of research, we may not finally succeed in describing vital phenomena in the 'conceptual shorthand' used by the physicist involving his ideal world of ether, atom, and molecule. At present we are far from such a consummation. The principle of adaptation is the only formula which will include all the phenomena of living beings, and it is difficult to see how this principle can be expressed by means of the concepts of the physicist." This book is really one for the advanced student or at any rate for one who has already studied physiology in a more elementary textbook. Book Ideals with general physiology, discussing the various properties of protoplasm, and the material and energetic bases of the body. The chemistry of the fats, carbohydrates, and proteins and the mechanism of organic synthesis are carefully presented with the aid of many graphic formulæ. The problems of osmosis, the properties of colloids, and allied subjects are discussed in satisfying detail. Book II deals with the mechanisms of movement and sensation, and Book III with the mechanisms of nutrition. The important recent contributions to the knowledge of the nervous system, as the subject of the autonomic nervous system, sensory localization, cerebellar function, etc., are all carefully discussed. The important advances in the knowledge of the physiology of the circulation, which knowledge lies at the basis of the latest clinical applications of the graphic methods of studying circulatory derangements, are accorded in this book an amount of space commensurate with their importance. The general practitioner who would seek to supplement whatever knowledge of physiology he was able to assimilate in his student days will find this book one which will not only furnish the newer facts, but will coordinate them with his clinical experience.

Aids to Tropical Hygiene. By Major R. J. Blackham, D.P.H. (London), R.A.M.C. Knight of Grace of the Order of St. John; of the Middle Temple, Barrister-at-law; Kaiser-I-Hind Medallist for Public Service in India; Divisional Sanitary Officer, First Division, Indian Army; Fellow of the Royal Institute of Public Health; Member of the Royal Sanitary Institute. Price $1.25. New York: William Wood & Company, 1912.

There are but few works on Tropical Hygiene, and the subject is generally neglected in the textbooks on Hygiene. The present work is small but of distinct value. The author discusses the following subjects: climate, air and ventilation, water and water supplies, food and feeding, clothing, sites, soils and houses, disposal of refuse, disposal of the dead, insects and disease, animal parasites, prevention of malaria, and disinfectants and disinfection. A useful list of references is added, and there are serviceable tables of (1) Tropical diseases with preventive measures, and (2) The distinctive characters of the more important species of flies. All who are interested in tropical diseases and conditions will find the present volume a useful addition to their library.

# Society Reports.

## WESTERN SURGICAL ASSOCIATION.

*Twenty-Second Annual Meeting, Held at Cincinnati, Ohio, December 20 and 21, 1912.*

THE PRESIDENT, DR. L. L. MCARTHUR OF CHICAGO, IN THE CHAIR.

(*Concluded from page* 181.)

**Intussusception.**—Dr. S. C. BEEBE of David City, Neb., said the recurrence of intussusception shortly after its reduction had been sufficiently frequent to make it necessary that the operation performed include such a fixation of the bowel or shortening of its mesentery as would prevent recurrence at this site. Whatever might finally be demonstrated to be the actual cause of death in obstruction of the bowels, experience had shown that drainage of the stagnant fluid in the gut above the point of obstruction promoted the recovery of the patient. Advanced cases of intussusception formed no exception to this rule, and in them provision for such drainage must be made. Threading the gut on a glass tube introduced into it through an incision in its lumen was unclean, time consuming, and involved more visceral manipulation than was admissible in our ideal operation. The method of stitching into the gut a large rubber catheter with rows of pursestring sutures after the manner of a Senn gastrostomy, as repeatedly described by a former president of this association, was decidedly superior and its principle should be included. Important as this drainage might be, it was of still greater moment that gangrenous tissue should be removed from the field of absorption. When it was present, resection of the bowel must be done; and as it frequently existed in the irreducible invagination, whether or not it showed upon inspection, it followed that irreducible intussusceptions must always be excised and the expedient of anastomosing the gut above with that below the obstruction or of simple enterostomy must never be adopted. In his paper he described a technique which best met the indications. It was the adaptation of well known methods with some variations that had seemed of sufficient value in his own work to warrant their presentation.

Dr. DANIEL N. EISENDRATH of Chicago said anyone who had operated on a case of intussusception in an infant and had seen the degree of shock which these children had, knew that the thing that would give the highest mortality. Where it was impossible to pull the intestines apart, it was much better, if the child was in any degree of shock, to bring the intussuscepted part out through an abdominal incision, and do an enterostomy to tide the child over for two or three weeks, and then do resection at leisure when the child was in good condition.

Dr. CLIFFORD U. COLLINS of Peoria, Ill., said these cases should be operated on inside of twelve hours if we expected to decrease the mortality very much. The general practitioner must be educated to bring these cases to the surgeon sooner than he had been doing.

Dr. WILLIAM D. HAGGARD of Nashville said the contention of the essayist, that enterostomy was extremely valuable in these cases as an adjunct, was sound practice, and he thought, moreover, it was preferable to the use of Moynihan's long tube. Those who had used this tube knew that while it was theoretically excellent, it was difficult to thread it through a number of feet of distended intestine, and whenever one touched the intestine the peritoneum broke, so that the use of the appendix was particularly to be commended as a drainage route for enterostomy.

Dr. BEEDE, closing, said he was glad that Dr. Eisendrath had been able to save some of these children by enterostomy, and then later excising or resecting the bowel. He had not been able to find a record of any such case in the literature he had consulted. If such was the base, he would like to know it.

**President's Address: Transplantation of Tissues.**—Dr. L. L. MC ARTHUR of Chicago said that given the appropriate conditions, any tissue might be transplanted, the difficulties increasing with the vascularity rather than the complexity of the structure, those structures requiring the least circulation proving the more successfully grafted. He instanced fat, a tissue made up of a delicate living reticulum, stored with an enormously disproportionate amount of fatty globules. For its existence and maintenance, it required little else than plasma and asepsis under body conditions. Hence it could be transplanted free and in almost any bulk, provided these conditions be maintained. For this reason, we might now look to see the cavities in bones filled, instead of with Mosetig Moorhof's plug or Beck's paste, by pads of living fatty tissue taken elsewhere from the patient, as was recently demonstrated at Garre's clinic in Bonn; or, as the author had several times done, deposit such fatty tissue in areas heretofore treated by Gersuny's paraffin injections, it being particularly adapted to filling out those greater deformities not amenable to paraffin. He gave as an example the cosmetic filling out of the deformity left after a partial resection of the lower jaw. This had given him most gratifying results. Encouraged by the successful transplantation of this tissue, till recently considered so liable to slough, he had stolen elsewhere from the patient an envelope of fatty fascia to protect the musculospinal nerve just released from the callus of a humeral fracture, or a nerve trunk just sutured after resection for neurofibroma. Again, the hygroma that developed after Murphy's interposition of fatty fascia, need no longer be obtained from a pedunculated flap taken from the immediate neighborhood of the joint often at the sacrifice of structure essential to a good result and adding a complication to the operation, but might be secured elsewhere. For the ankylotic hip or knee, the operation could thus be remarkably simplified.

**An Experimental Study of the Therapy of Shock.**—Drs. M. G. SEELIG, J. TIERNEY and F. RODENBAUGH of St. Louis contributed a joint paper on this subject. It was attempted to check up the work of Professor Yandell Henderson on shock. Henderson's theory of shock was that this symptom-complex was due to a lack of carbon dioxide in the circulating blood. The essayists, therefore, attempted by direct methods to increase the $CO_2$ blood content. For this purpose they introduced intravenously into shocked dogs varying quantities of a molecular (8.4 per cent.) solution of sodium bicarbonate. Sodium bicarbonate was dissociated into sodium carbonate and carbon dioxide by three elements in the blood, viz., serum albumin, hemoglobin, and acid sodic phosphate. The quantity of the solution used varied from 5 c.c. to 200 c.c., and the condition of the dogs varied from normal to a state of profound shock. An analysis of the results obtained in a large series of experiments on dogs showed that sodium bicarbonate was a powerful blood pressure raising salt, the rise in blood pressure persisting over a fairly long period of time. Likewise, this salt markedly increased the amplitude of the heart beat, though it had no appreciably constant effect upon the rate of the heart beat. The depth of respiration was always increased by the infusion, though the rate of respiration varied within wide limits. After it had been definitely determined that the above noted effects were constant, it was attempted to determine by what mechanism the rise of pressure was occasioned. To this end the bulk of fluid injected, the alkalinity of the sodium bicarbonate, the hypertonicity of the solution, and the free $CO_2$ resultant from the injection were studied separately. The authors reached the conclusion that bulk and hypertonicity played a minor role in raising the blood pressure; that alkalinity played a more important part, but that it seemed most probable that some additional undiscovered factor was responsible for the pronounced rise. Whatever this factor was, it seemed to act directly on the heart, even when this organ was isolated from its central nervous system relationships. The authors were not able to attribute any of the pressure effect of the infusions to the increased $CO_2$ content of the blood.

**Ostitis Fibrosa Cystica.**—Dr. JAMES F. PERCY of Galesburg, Ill., reported a case, with lantern demonstration, on which he had operated, and reviewed the literature. He said the course of the disease was persistently chronic. The osteoporosis, due to the persevering destructive action of the osteoclastic cells, weakened the bony framework to the point of deformity, suffering, and uselessness. It was this that explained the infrequency of pathological fracture which, according to Pfeiffer, occurred twenty times in his report of 49 cases. Curiously, this author (Pfeiffer) advised against operative measures because the disease was essentially not malignant. He would use the knife only for the purpose of diagnosis or where the pain was excessive. Voit, however, insisted upon radical treatment. The case reported by the author had been greatly relieved by the operative procedures followed. The pain had disappeared and the sense of insecurity and weakness in and about the hip had disappeared. The deformity had not been overcome, but this could be left to subsequent surgical treatment if it seemed wise to attempt it. The most important problem was the method to be pursued in this case where the iliac bone, especially the right, was so extensively involved. This question must also arise when the disease occurred in the small bones of the foot and hand or in the skull. It was necessary to remember that the disease always involved the endosteum and not the periosteum, and this fundamental pathological fact must be the basis of

interference to arrest the destructive process. The indications for operation could safely be enumerated as follows: (1) Interference with function and the development of deformity. (2) Pressure upon important vessels, nerves, and organs. (3) Prevention of pathological fracture from a large osteoporosis resulting from the disease. When the pernicious character of the pathology was considered, especially in relation to the ruinous work of the osteoclastic cells, a permanent recovery could be obtained in no other way than by radical operation.

**Ventral Tumors of the Sacrum.**—Dr. Arthur Aver Law of Minneapolis, after discussing the embryology of these growths, reviewing the literature, and reporting a case, presented the following summary and conclusions: The large tumor showed a loose, rapidly growing connective tissue stroma in which were nests of embryonic cells growing in syncytium-like masses and suggesting malignancy in their manner of growth and appearance. Areas of hemorrhage, necrosis, and calcareous degeneration demonstrated the atypical character of the tissue, its rapid development, and imperfect blood supply. The smaller tumor suggested a neuroma in its general characteristics, although neuroglia fibrils had not yet been demonstrated. That the tumor sprang from some misplaced remnants of the terminal portions of the neural tube seemed a logical conclusion. That portions of it had developed abnormal powers of proliferation and showed signs of malignancy change, while other portions had in an imperfect manner reproduced the adult type of nerve tissue, was the only explanation which apparently explained these rather widely diversified tumor masses.

Dr. E. S. Judd of Rochester, Minn., stated that since Dr. Law had called his attention to this interesting case, he had reviewed the cases of the Mayos of retroperitoneal tumors and found in the list five cases that, in some respects, were similar to Dr. Law's case. The five cases were operated upon, three by W. J. Mayo, one by C. H. Mayo, and one by himself. The first patient was a woman, 44 years of age, who came to the hospital complaining of constipation and bleeding from hemorrhoids. A tumor the size of an orange could be felt per vagina and rectum; it came to the midline in the pelvis and extended to the right side. Examination otherwise was negative. Wassermann was negative. Operation November 21, 1912. Abdominal incision. Retroperitoneal tumor apparently growing from the right wall of the sacrum, about the second foramen, bulging out as a tumor the size of an orange under the periosteum and deep fascia, lying between the upper rectum and lower sigmoid and cervix, completely filling that portion of the pelvis. Abdomen opened; posterior peritoneum and floor of the pelvis to the right opened; tumor enucleated and most of the capsule removed. The tumor resembled hypernephroma. It appeared to be broken down, opening in the sacrum the size of the end of the finger near the third foramen through which the pedicle of the tumor seemed to go. Report of pathologist: Inflammatory. The second patient was Mrs. H. L. N., aged 57. She came June 4, 1912, for a rectal tumor; incontinence; six months ago hemorrhage from bowel; pain and rectal spasm frequently since; bowels gradually became obstructed, and now she is almost unable to get bowel movements. Lost weight, ten pounds; had radiating pains from sacral area to thighs and vagina. Examination disclosed a tumor posterior to the rectum. Operation: Posterior incision at the lower end of the sacrum and all of coccyx removed which was involved in the tumor. Tumor, the size of an apple, was apparently a sarcoma of the anterior surface of the lower end of the sacrum and upper coccyx. Third, fourth and fifth sacral vertebræ were involved. Tumor had perforated posteriorly and a large amount of soft sarcomatous tissue had escaped into the hollow of the sacrum. Report of pathologist: Giant-celled sarcoma. The three other cases were detailed by Dr. Judd.

Dr. Jabez N. Jackson of Kansas City, Mo., had had opportunity to observe two cases of ventral tumor of the sacrum of two different types. One was very interesting from the fact that the woman was under observation primarily for the purpose of cesarean section. She was 26 years of age. She had a tumor behind the rectum which was recognized by a country doctor some time before pregnancy and he warned her at the time not to permit herself to become pregnant. She was in labor forty-eight hours, but as things did not progress as they should, he at once brought her to Kansas City for operation. Cesarean section was done, followed by hysterectomy. The tumor presented itself a little to the left of the rectum, and it turned to the right slightly as well as anteriorly. In splitting the peritoneum the tumor was enucleated without practically any bleeding, and after enucleation it showed no apparent point of attachment whatsoever, except when shelled out the whole anterior surface of the formation of the sacrum was revealed, but it was enucleated without the presence of a pedicle or without definite knowledge as to its original point of development. It was a single solitary cyst which on pathological examination was found to be a simple cyst without a determination of what elements could have been the original focus. The second case that came under observation was a man, 45 years of age, who complained of pain in the lower pelvis, and particularly about the rectum during defecation, and of some pains which radiated down the limb, until his physician thought there might be some trouble about the hip joint. On rectal examination a tumor could be outlined near the lower end of the rectum about the size of a small orange. In operating he made an incision laterally, but upon entering the tumor found the fluid sort of cystic, possibly purulent. It seemed some inflammatory secondary condition had taken place, and the wall was so friable it was impossible to make any enucleation whatsoever. He removed certain portions of it and packed for drainage.

**How Much Pathology Can the Gall-Bladder Have and Still Functionate?**—Dr. B. B. Davis of Omaha pointed out that certain conditions found often at operation were bound to destroy normal function for all time. Undue narrowing or complete obliteration of the lumen of the cystic duct made a continuation of the function of the gall-bladder impossible. If the obstruction was incomplete, bile would slowly flow in, but the process of emptying was so retarded that stagnation, which always invited infection, was sure to occur sooner or later. Although safe and efficient delivery of the bile through the hepatic and common ducts into the duodenum could be carried on by the other forces without its aid, it could be done more effectually and with less liability to damming up of the current when accelerated by a perfectly functionating gall-bladder. He would, therefore, be the last to recommend the indiscriminate removal of this organ. It ought never to be done unless so badly damaged that its function would be permanently lost. When one met with so many patients whose gall-bladders had been drained, but who were not cured, there seemed to be something still to be said. The fact stood out that drainage operations were not followed by the uniformly good results that ought to be obtained. Patients too often felt a regret that they did not keep away from the surgeons. It was his opinion that many of the unfavorable results might be avoided by a more thoughtful consideration of the capacity of the gall-bladder with which one was dealing to carry on its functions.

Dr. Charles H. Mayo of Rochester, Minn., said that very often we took out the gall-bladder when we should leave it. When a patient complained afterward and came back for a secondary operation, he said the gall-bladder ought to have been removed in the first operation. In about one-half of such cases we would find the gall-bladder ought to have been removed primarily. In the other half we would find an enormous mass of adhesions; we would find the duodenum adherent to the liver and scarred; the pylorus adherent to the gall-bladder and margin of the liver. We would say, "Well, I wish I had done something to prevent those adhesions," not thinking at the time that those were the adhesions that made secondary symptoms; that that particular gall-bladder was not diseased, but that adhesions occurred on account of bad surgery and of not utilizing fat, as suggested by our president (Dr. McArthur) in his address to prevent them.

**Pyelotomy for the Removal of Renal Calculi.**—Dr. Daniel N. Eisendrath of Chicago said the method of exposure and of bringing the kidney into the wound did not differ in any manner from that employed for nephrotomy. In order to perform a pyelotomy, one must be able to lay the kidney completely on its anterior surface, either upon the skin edges of the incision, or, at least, to be able to gain access to the posterior aspect of the renal pelvis without much tension on the renal vessels. If the pedicle was short, or there was much fixation of the kidney by adhesions, pyelotomy was out of the question, and too much traction under such conditions would surely result in disaster. In the majority of cases, however, pyelotomy was possible if the incision was not too small and the wound edges well retracted. Through the pyelotomy incision one could introduce the index finger and palpate the entire interior of the pelvis. The extraction of the calculi lying loose in an ampulla or one of the main divisions of a bifid pelvis was very simple. The advantages of pyelotomy were: (1) It was the simplest and least serious method for the removal of calculi lodged at the junction of the ureter and renal pelvis, or for small or moderately large calculi, either free in the

ampullary type of pelvis or in a primary calyx of a bifid or trifid type of pelves. (2) It was the best method for calculi in one or both pelves of a horseshoe kidney, as well as in bilateral cases, especially in those complicated by anuria. (3) Hemorrhage was far less likely to occur either during or after pyelotomy than in nephrotomy. (4) Bimanual palpation of the pelvis and parenchyma lessened the chance of overlooking a calculus. (5) Pyelotomy could be much more rapidly done, and the period of convalescence was much shorter than in nephrotomy. It was seldom more than ten to fourteen days, in his experience. The disadvantages of pyelotomy were: (1) Pyelotomy was contraindicated when the kidney was fixed by adhesions or the pedicle was short, or if extensive infection be present. (2) A fistula might persist after operation. (3) The danger of bleeding either during or after operation from the peripelvic vessels, although slight, must always be borne in mind. Pyelotomy was destined to become an active competitor with nephrectomy in the majority of cases.

Dr. William Jepson of Sioux City, Iowa, said that nine years ago he nearly lost a patient from continuous hemorrhage, which began some eight or nine days after nephrotomy. The hemorrhage ceased from time to time, but reappeared, until it was five or six weeks before danger was passed and his fear was allayed. This was followed a year and a half afterward by another patient, a young man, who died. He had never done a nephrectomy since that time for the purpose of removing a calculus in the kidney. He immediately perfected himself in the technique of operating through the pelvis itself for the removal of stone from the ureter or kidney, if accessible.

Dr. A. W. Abbott of Minneapolis said that one of the greatest arguments in favor of the position taken by the essayist was the irreparable damage done to the kidney by any incision into it. If we incised it, we had to sew it up. It had been shown that the injury by the connective tissue formation after incision and fatty degeneration that followed, also the same process that took place after suture of the kidney, should make it inadvisable to cut the kidney unless we had to.

**Observations on the Radical Cure of Inguinal Hernia.**—Dr. William Hessert of Chicago said our choice of operative technique should be determined by the anatomical findings. We had all seen cases in which it would have been impossible to perform a typical Bassini operation. Owing to the absence of the rectus, the former could not be brought down to Poupart's ligament, without creating too much tension. Either the muscle would tear at once or necrosis would occur later. Attention had been called to the fact that this inner portion of the canal should be especially fortified against recurrence. The technique which was best adapted to meet the requirements of these cases was the imbrication modification of Andrews. By bringing down to Poupart's ligament the edge of the fascia of the external oblique and as much of the muscle as possible, a very firm covering for this weak area was secured; this weak area was further fortified by the overlapping of the lower flap of fascia. In cases where the triangle was especially large, good tecnique would be found of service. By incising the edge of the rectus sheath, the fibers were exposed and a portion of the muscle could be brought down and sutured to Poupart's ligament, thus supplanting the conjoined tendon which was absent. The operation could be completed by following the Andrews technique. Conclusions: (1) The conjoined tendon was deficient or absent more commonly than had been generally taught. (2) This anomaly supplied an important predisposing factor in the development of direct hernias, and probably played a certain rôle, though a minor one, in the etiology of oblique hernias. (3) The presence of this defect precluded the performance of the Bassini operation as a routine, except in children. (4) The Andrews imbrication method had fulfilled the indications regardless whether the tendon was present or absent. The Bloodgood transposition of the rectus was an excellent aid when required.

Dr. C. M. Nicholson of St. Louis stated that in probably five cases out of ten that had come under his observation of hernia there had been a separation of the aponeurosis of the external oblique, and the intercolumnar fibers could be seen plainly a distance of an inch and a half. Every one who had dealt with inguinal hernia had noticed this. If the trouble were due in a large percentage of cases to the absence of any structure, it seemed surprising that clinically we got such excellent results by doing some modification of the Bassini operation, probably infolding in accordance with Ferguson's suggestion. He felt very sure that in something over five hundred herniotomies, not strangulated or complicated, but simple hernias, he had seen but three recurrences, and these were all due to a condition other than that described by the essayist. All three were in children and were due to a lack of development of the external oblique muscle. He had therefore come to the conclusion that the cause of hernia was not due to a preformed sac except in that variety of hernia which was congenital, that is, irrespective of the time it formed.

Dr. A. E. Benjamin of Minneapolis thought the essayist was right in his conclusion that the conjoined tendon was very often absent. It had been his practice in these cases to transplant the fat; after tying it off he passed it back of the transversalis and brought it up high, so as to have the intraabdominal pressure in the sac after that come against the transversalis muscle. In that way we took off the strain, but the fibers of the transversalis and internal oblique he had brought underneath Poupart's ligament with modified Halsted mattress suture, bringing that out through the skin. This frequently was done because at the time he first developed the operation he did not have suitable catgut or suture material which he could rely on. At the present time this did not obtain.

Dr. F. Gregory Connell of Oshkosh, Wis., agreed as to the necessity of operating on the other side where there was a slight bulging, even though there were no demonstrable hernia, as he had had the same experience as others of a subsequent hernia following the repair of the side where it had developed. He had met with the absence of the conjoined tendon. In these cases there was a direct hernia of the deep epigastric vessels formed under the internal margin; the internal ring, while not bulging, was below. We might call it a ventral hernia rather than inguinal, as it was not inguinal in the strict sense of the word in that it did not come through the inguinal canal.

Dr. M. L. Harris of Chicago stated that as the result of personal observations he was fully convinced that all hernias that developed in the active period of life were congenital in origin. By this he meant they were due to congenital defects. He would exclude the hernias—the simple hernias—that developed in the aged, coming at a period of life when there was general atrophy and wasting of the tissues, as in old people with chronic bronchitis, emphysema, enlarged prostates, etc. Every hernia developing in the inguinal region during the active period of life had its origin in a congenital defect. He had had the opportunity of operating on several so-called traumatic hernias that appeared soon after an injury or a fall. In every one of these he had found congenital sacs, and there had never been any difficulty in determining after the operation that the sac was of congenital origin. The absence of the conjoined tendon was a material factor in the causation of hernias, as was pointed out in an article which appeared two years ago from Russia. It was discovered that during the last Russian war an unusually large number of the conscripts constantly appeared with ruptures, who were otherwise healthy young men, who ought to be sent and were capable of going into service, but who escaped by reason of having ruptures. The authorities investigated the matter and after getting confessions from some of the subjects, it was discovered there was a regular place where these young men went and had these hernias produced, and they were produced by a young doctor who had discovered that by passing his finger up into the external ring and forcibly tearing the conjoined tendon from its insertion, these young men would all develop hernias within a short time. That demonstrated clearly the influence of the conjoined tendon in producing hernia.

Dr. Daniel N. Eisendrath of Chicago, said that his observation of this class of cases had taught him that it was possible to make a diagnosis before operation, so he made it a rule to ask the patient to let him operate on both sides, even though on the other side no hernia had appeared, because sooner or later a hernia would appear on the other side, and the patient might feel that there had been some negligence on the part of the surgeon in having operated on one side only, because he could not associate that with the fact that he had continually weak muscles there. In addition to the fact oftentimes of lack of development of the conjoined tendon or atrophy of the fibers of the internal oblique, this condition was found when the conjoined tendon was fairly well developed. It was found in stout individuals who had attenuated oblique muscles, where there was practically only white muscle and lying between the white fibers we found quite a lot of fat. What good did it do to perform the old Bassini operation? To do so would invite disaster. If one sutured this attenuated internal oblique, this weak or imperfect conjoined tendon,

to Poupart's ligament and put the cord on top of it, he would have trouble or a recurrence, no matter whether he transplanted it or not. Those who were acquainted with the operation had adopted as a routine the Wyllys Andrews method of imbrication of the muscles because it had a tremendous advantage.

Dr. Hessert, in closing, said he did not claim that the absence of the conjoined tendon was the cause of hernia, except as having a certain bearing on the formation of direct inguinal hernias. He thought Dr. Harris put the matter tersely when he said that the hernias which occurred during young adult life were based on certain developmental defects. It was either a congenital hernial sac or some developmental defect, such as absence of the conjoined tendon or peritoneal muscles or fascia in this region. Added to that, it was essential to have the predisposing factors which brought down the hernia.

**Spinal Anesthesia.**—Dr. J. W. Andrews of Mankato, Minn. said ether was the best anesthetic to use. For local anesthesia cocaine was the best anesthetic. Cocaine was likewise the best spinal anesthetic. The solution used should be weak, one-half of one per cent. to one per cent. was strong enough. The lumbar was the regional point of election for spinal puncture. Under spinal anesthesia the tissues would not bear pulling or tearing. Pulling or tearing or roughly handling living tissue was bad surgery. Busy surgeons could not use spinal anesthesia. The dangers of spinal anesthesia were practically none, and the advantages very few.

Dr. James E. Moore of Minneapolis said the chief objection to spinal anesthesia was its danger. The most recent case in which death occurred on the table following spinal anesthesia was that which occurred at the meeting of the Clinical Congress, of Surgeons in New York City. Spinal anesthesia was first suggested by Corning, was first put into practice by Bier in 1898, who abandoned it for a time on account of the mortality connected with it. In 1903-4 stovain and novocain were introduced. At the present time novocain was the favorite drug for this purpose. In the University of Minnesota they used no other drug for local anesthesia or for spinal anesthesia. So far, they had had no mortality and no uncomfortable symptoms. They had used it locally for hernia operations and the like. He had used it more in private practice than in the University Hospital.

Dr. M. L. Harris of Chicago differed with the essayist that the element of time was not a factor in the ill-effects of an anesthetic. One could kill any animal by keeping him under an anesthetic for a certain length of time, and if the quantity was the same the animal would inevitably die. The changes were in direct proportion to the time in which the anesthetic was given.

Dr. H. G. Wetherill of Denver said the time had come when chloroform as a general anesthetic ought to be abandoned. Our present knowledge of the late poisonous effects of chloroform, as originally cited by Guthrie in London and Stiles of Edinburgh, and by Bevan and Favill in this country, had played an active part in taking chloroform out of our hospitals as a general anesthetic, as it should do, because it was known, notwithstanding the enormous danger of chloroform in comparison with ether and other anesthetics, it produced death two or three days afterward.

Dr. A. W. Abbott of Minneapolis recounted some experiments in reference to ether as compared with nitrous oxide, and said that for two or three years he had kept records of these cases in reference particularly to the results on the kidneys. In many instances he had been able to secure the urine in from ten to fifteen minutes after ether anesthesia was begun, and he found a slight albuminuria was produced. It was not 1 per cent. or 10 per cent., but every one of the cases had had a slight albuminuria. As a general thing, casts began to show in the urine taken in the course of an hour. His experience in that line directly corresponded with what Dr. Harris had said, namely, that an amount of injury to the kidney followed in proportion to the length of time one gave the anesthetic. The longer you gave it, the greater the amount of albumin, and the more abundant the casts. He had the records of 100 of these anesthesias, and he believed what he had stated was absolutely correct. This applied in a minor degree to nitrous oxide with oxygen, which he had used a great deal. It was followed by the same disturbances. Whatever anesthetic we used, we were going to have kidney complications, and that was a good reason why we should get through with an operation as quickly as possible and not keep the patients under the anesthetic any longer than possible.

Dr. S. C. Beede of David City, Neb., said there was nothing that succeeded like success. He believed in ether anesthesia because it gave the best results. Yesterday he stated that there were only two cases reported in the literature at his command of the successful treatment of irreducible invagination in a child under one year of age. Conversation with a number of members since then had confirmed that statement. Both of those cases were operated under spinal anesthesia. While spinal anesthesia was limited, it still had a field.

Dr. L. L. McArthur of Chicago in speaking of the toxicity of novocain and cocaine, said he would like to call attention to the fact that it took seven times as much novocain per kilogram of body weight to kill as it did cocaine.

So far as their anesthetic properties were concerned, they were practically identical. Novocain was now the drug universally used on the Continent and in England, instead of cocaine, on the basis of its toxicity.

**Final Results in Hypophyseal Surgery.**—Dr. Allen B. Kanavel of Chicago reported a case of typical Froelich type of hypophyseal disease, suffering with marked signs of intracranial pressure; operated upon two years ago; infranasal route, cyst evacuated, recovery, result of feeding pituitary gland over two years. The indications for operation in cases of hypophyseal disease might be classified as absolute and relative. Operation was absolutely indicated in those cases in which the tumor immediately jeopardized the life of the individual or was causing progressive blindness. It was relatively demanded when because of perverted, or increased, or decreased secretion, the wellbeing and, ultimately, the life of the individual was threatened. Therefore, if the tumor was growing rapidly or had grown to a large size, or if a cyst had suddenly filled, we would have pressure symptoms both locally and generally that would imperatively demand intervention. As the safety of the operation increased, the field of the relative demand would be broadened. Acromegaly should be treated more conservatively, particularly since many of the cases had passed over into the stage of hypopituitarism. As the safety of surgical procedures grew, operation should be attempted in the early stages of the disease before the growth had left the sella. The more complicated and late cases and those with atypical signs should be treated medically until the results in the typical cases were well established.

**Pregnancy in the Rudimentary Cornu of Uterus Unicornus and Report of a Case with a Full Term Fetus.**—Dr. E. P. Quain of Bismarck, N. D., said a correct diagnosis of pregnancy in the rudimentary cornu had been made in but a few instances before operation. The usual diagnosis made was extrauterine pregnancy. In view of the similarity of treatment, this mistake was not serious. To call this abnormality a uterine fibroid or an ovarian cyst, as had been done a few times, might have dire results. The important diagnostic points to be determined were: (1) Whether or not a pregnancy existed. (2) Whether the uterus unicornis could be palpated as distinct from the tumor, but attached to it by a pedicle opposite the internal os. (3) Whether intermittent contractions in the rudimentary cyst wall were palpable as in a normal pregnant uterus. (4) A possible palpation of the round ligament external to the tumor; this would eliminate tubal pregnancy. The treatment was that of ectopic pregnancy in general. The removal of the gravid rudimentary cornu would be indicated when diagnosed, whether the fetus was dead or alive. If diagnosed in the seventh or eighth month, the question might be raised whether it would be advisable to wait in an attempt to save the child. It was to be remembered that a pregnancy in a rudimentary cornu was less liable to rupture than were the other varieties of ectopic pregnancy. But no temporizing measures should be practised unless the patient be put to bed and within instant reach of the operating room. At operation it would seem wrong to exercise a sterilizing technique on the normal tube. Normal pregnancies had followed in uteri unicornes after removal of the rudimentary side, and no instance of tubal pregnancy was recorded.

**The Growth, the Death, and the Regeneration of Bone.**—Dr. H. G. Wetherill of Denver spoke of the radical differences of opinion which characterized the teaching of the theory of the growth and regeneration of bone. Macewen not only denied to the periosteum an osteogenetic function, but assigned to it a function of a diametrically opposite character, that chiefly of a "limiting membrane" for the osteoblasts to prevent their overgrowth into the soft tissues. As an example of the eccentric growth of bone through rents in its periosteal envelope in an untreated fracture, the author presented a specimen from a young elk he killed in Colorado in 1892. The unconfined osteoblasts distributed through the periosteal rent by the constant use of the animal's leg had produced a large amount of exuberant callus in addition to that required to

unite the fragments. Another striking example was the formation of a bony wall for a false aneurysm where the ends of the fractured bone had at once lacerated the limiting periosteum and a large artery. The osteoblasts swept from the bone through the rent and carried by the blood stream to the side wall of the aneurysm formed plates or plaques of bone upon it, though they be entirely disassociated from both the bone and the periosteum. The well-known importance of the epiphysis and of the plates of the cartilage lying between the epiphysis and the diaphysis in their relation to the growth of the diaphysis was experimentally confirmed, as was also the protection afforded by this cartilage against the diffusion of infection. Viewed from Macewen's standpoint and in his light, the author found the two typical cases, quoted in his paper, confirming his other observations under similar conditions, and he was quite ready to accept the new doctrine and adapt himself to it in its actual application to the day's work.

**Coexisting Infection and Sarcoma of the Thyroid.**—Dr. Miles F. Porter of Ft. Wayne, Ind., said sarcoma of the thyroid was very rare, and sarcoma complicated with infection still more rare. Only 11 cases were reported in the United States to June, 1906. A previous history of goiter existed in 53 per cent. of cases of malignant thyroid (carcinoma and sarcoma), and in half of these for more than ten years. Two-thirds of the cases were in women, and 53 per cent. of the cases were between forty and sixty years old. Metastasis of sarcoma of the thyroid by way of the lymphatics was not infrequent. Four additional cases of sarcoma were reported from the literature and one in the author's own practice in a boy of eleven years with metastasis in cervical lymphatics. The spindle cell variety was the most common. No other case complicated by infection was found in the literature. The neighboring bones were frequent seats of metastasis. It was difficult to differentiate between the round cell variety and lymphosarcoma. Complete destruction of the gland tissue by sarcoma was quite common. Sudden growth of an old goiter, especially if accompanied with pain, was significant of malignant invasion, as was hemorrhage into a goiter. Careful examination of all goiters removed would develop the fact that malignancy was more frequent in the thyroid than it was now supposed to be.

**Observations on German Surgery.**—Dr. Charles H. Mayo of Rochester, Minn., said the twenty-five university centers in Germany might be classified according to equipment, wealth, numbers of students and large centers of population. Their hospitals were large, usually constructed on the pavilion system. Their beds numbered from hundreds to a few thousands. The hospitals were all well equipped with modern Röntgen apparatus, and this department of diagnostic work seemed to have been developed to a wonderful degree of perfection. Much care and thought had been given to the arrangement of the operating rooms, and especially to the lighting system, several of them having the powerful arc focused on to mirrors. In all the operating rooms were a great many assistants, and after the essential details had been carried out by the master surgeon, the case was passed on to the first, second, and third assistant surgeon who completed the work. The surgeons were exceedingly well prepared for their work. They had served long apprenticeships, and they all took pride in speaking of the well-known men with whom they had studied and served as assistants. The excellent team work of those engaged in diagnosis in all departments was worthy of note, each diagnostician following his cases to the operating table to witness the conditions found upon exploration. German surgeons had a great liking for reconstructive work, and much could be learned in a study of their bone, joint, and plastic work. In several clinics he witnessed the entire transplantation of joints immediately upon their removal from amputated limbs to replace ankylosed ones. Various forms of local anesthetics were used and the method had been highly perfected. German surgery might be spoken of as a "school of surgery," and had more or less dominated the surgery of the world. The German surgeon was most efficient. While his surgery had originally developed almost entirely from the laboratory side, the clinical work to-day had certainly advanced remarkably. The methods of hospital support and control had created a system which was adapted to the masses, in contrast to the system in this country which considered individuals. Although many of their methods were not adapted to our institutions and people, they were well worth a visit from any of our surgeons since there was much that could be learned from them.

**The Present Status of the Radical Abdominal Operation for Cancer of the Uterus.**—Dr. Reuben Peterson of Ann Arbor, Mich., stated that the chief reason for the unpopularity in this country of the radical abdominal operation for uterine cancer was its high primary mortality. Surgeons were not accustomed in these days of highly perfected technique to a primary mortality of from 20 to 50 per cent., which would be a fair estimate of the mortality of the radical abdominal operation, if all reported and unreported cases could be collected. Surgeons necessarily must be content with such a high mortality in emergency operations, neglected cases where the knife held out the only hope of saving life. Under such circumstances the surgeon consoled himself with the thought that without operation it was sure death for the patient within a few hours or days, and that every life saved was so much gain. The present status of the radical operation for cancer of the uterus in this country was directly dependent upon early diagnosis of the disease. Unless patients could be operated on earlier, we had about reached the limit of what could be accomplished by the operation, except as the primary and end results might be improved somewhat as the technical skill of the individual operators increased. The main points to be emphasized were: the poor results obtained in the operative treatment of carcinoma; the possibility of improving the results of such treatment by earlier recognition of the disease by both the profession and the laity; the necessity of inaugurating a campaign of education on carcinoma through committees appointed from the various national, surgical, and gynecological societies, and finally the desirability of having this society be the pioneer in this movement.

**Some Phases in the Modern Treatment of Fractures.**—Dr. W. D. Haines of Cincinnati, said that given a competent surgeon with good hospital facilities, those fractures which might be reached in which the ends of the broken bone could not be kept in proper relation to allow union to take place with a reasonable assurance of overcoming marked deformity and the restoration of function, should be subjected to some type of open method in their management; that fractures occurring in the long bones should, after complete reduction, show crepitus as a final test for freedom from interposed soft structures; in the absence of this confirmatory evidence, union will depend upon examination through an incision and removal of the interposing structures: that all open fractures, after proper cleansing, should be freely exposed, and reduced and retained by appropriate mechanical means. Finally, that ununited or old fractures in which union had taken place at a faulty angle, inducing pain and loss of function, should be subjected to operation.

The following papers were also read: "Fracture of the Carpal Scaphoid," by Dr. Joseph F. Smith, Wausau, Wisconsin; "Temporo-Maxillary Ankylosis," by Dr. D. W. Basham, Wichita, Kansas; "The Application of a Protected Gauze Pack Used as a Quarantine in Certain Abdominal Operations," by Dr. R. C. Coffee, Portland, Oregon; "Two Cases of Obstruction of the Bowels from Unusual Causes," by Dr. Clifford U. Collins, Peoria, Illinois; "Boning of the Thoracic Precardial Wall in Certain Affections of the Heart," by Dr. John E. Summers, Omaha, Nebraska; "Bilateral Cerebral Abscess Involving the Motor Areas," by Dr. Warren D. Dennis, St. Paul, Minnesota; "A Method of Bone Plating," by Dr. Carl E. Black, Jacksonville, Illinois.

**Officers.**—The following officers were elected: *President*, Dr. Jabez N. Jackson, Kansas City, Mo.; *Vice-Presidents*, Dr. Joseph Rilus Eastman, Indianapolis, and Dr. M. G. Seelig, St. Louis; *Secretary-Treasurer*, Dr. Arthur T. Mann, Minneapolis.

St. Louis, Missouri, was selected as the place for holding the next meeting; time, December, 1913.

---

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held January 16, 1913.*

The President, Dr. William M. Polk, in the Chair.

This meeting was held under the auspices of the Section on Orthopedic Surgery.

**An Exposition of the Abduction Treatment of Fracture of the Neck of the Femur.**—Dr. Royal Whitman read this paper which was illustrated with lantern slides of *x*-rays. In speaking of the anatomical basis of the treatment he stated that the normal inclination of the head of the femur of about 130 degrees permitted a range of abduction of the hip of about 40 to 50 degrees, a movement that was directly checked by contact of the upper border of the neck with the projecting rim of the acetabulum. During the movement of abduction the head of the femur glided downward until its lower third emerged from the acetabulum and distended the lower part of the capsule. At

the limit of abduction, under anesthesia, the base of the neck was in contact with the rim of the acetabulum, the tissues covering the trochanter were apposed to the tissues covering the pelvis, and the capsule was tense. It should be evident that any change from the normal, either in the forward, backward, or upward inclination of the femoral neck, must induce a corresponding change in function. Shortening of the neck or loss of its normal angle would, for example, limit the range of abduction, and this limitation was almost always present after fracture of the neck of the femur treated in the conventional manner, even when union had been attained. The treatment should be adapted to the anatomy of the part. In complete fracture of the neck of the femur, the limb was usually shortened, somewhat fixed, rotated outward, and often slightly abducted. Thus, the outer fragment was turned forward, displaced upward, and usually lay on a lower plane than the head. As one had no control over the inner fragment, contact could be assured only by adjusting the outer fragment to it. This was accomplished as follows: The patient having been anesthetized was lifted to a sacral support, the shoulders resting on a box of equal height, while the extended limbs were supported by two assistants. The assistant holding the uninjured limb then abducted it to the anatomical limit to illustrate the normal range, which varied in different individuals and at different ages, and incidentally to fix the pelvis by direct bony contact. The operator first flexed the thigh to disengage the fragments. The assistant then extended the limb and by manual traction overcame the shortening, as demonstrated by the relation of the trochanter to Nélaton's line, and by measurement. He then, under traction, abducted it to the normal limit, the operator meanwhile lifting the thigh from beneath. Inspection should now show absolute correspondence between the extended limbs, as to abduction, rotation, length and position of the trochanters. In this attitude the injured part was securely fixed by a plaster spica extending from the nipples to the toes. The advantages of the abduction treatment should be obvious to one who understood the mechanism of the joint. In abduction the outer fragment was turned downward and inward toward the inner fragment. In full abduction under traction, the capsule was made tense, and being attached about each fragment this tension would align them. At the limit of abduction the trochanter was brought into contact with the tissues covering the pelvis, or if the fracture was near the head the outer fragment was engaged beneath the rim of the acetabulum, thus providing a direct check against displacement. In abduction the direction of the muscles was so changed that the contraction could no longer displace the fragments. Finally, the attitude of abduction, which was so directly opposed to that indicative of deformity and symptomatic of weakness, was the attitude most favorable to restoration of function when support was removed. Attention was especially called to the sequence in manipulation. 1. Disengagement of the fragments. 2. Complete reduction of shortening by traction in the line of the body. 3. Abduction to a degree that should make the capsule tense. 4. Fixation in complete extension. So-called impacted fractures might be treated in the manner described, the deformity being readily reduced by manual traction. True impaction was very rare; what passed for impaction was usually a fracture with but slight displacement. Another type of so-called impaction was the incomplete fracture. Such and similar deformities might easily be corrected by the aid of slight leverage, as follows: Normal abduction must be limited in direct proportion to the lessened or lost angle. Thus the range of abduction under anesthesia was checked by contact of the neck with the upper border of the acetabulum, a contact that fixed it. Now under steady traction aided by downward pressure on the projecting trochanter the limb was still further abducted, with the aim of overcoming or lessening the deformity. In other words, the deformed neck lay in a plane representing normal abduction while the shaft was in the median line. The shaft was therefore abducted until the normal relation was restored, at least to the degree that was practical. When this was accomplished, a plaster spica was immediately applied. This method, in which secure support was at once applied, was both safe and effective. The reduction, or at least the lessening of deformity, should be as much a matter of routine in the treatment of this as of any other fracture, since otherwise, shortening, insecurity, and discomforts were practically inevitable even when union was attained. In the classical but unusual cases of true impaction, corrective manipulations might not be indicated. In the treatment of every variety of this fracture a thorough understanding of the principles of treatment and common sense in their application were in the absence of skill and experience essential. Dr. Whitman referred to various unfavorable criticisms that had been made of this abduction treatment and showed that they were mostly founded on misconceptions. The treatment of this fracture by the abduction method was more difficult than any of the routine surgical methods because of the lack of training and experience on the part of those who undertook it. The intelligent novice, however, who understood the principles of the method and had sufficient knowledge of typographical anatomy to apply it correctly could treat the fracture with a better prospect of success than by any of the time-honored methods with which he might be familiar. When this fracture occurred in young subjects it was usually one of the neck or of the epiphyseal junction. In either form the abduction method was essential. In the reduction of deformity in the epiphyseal form the manipulations of abduction and inward rotation must be forcible and persistent. If the case was one of long standing with forward and upward displacement of the neck in relation to the head, an open operation was required to properly oppose the fragments. The abduction method was not only the most efficient, but the most comfortable and the least dangerous of any treatment of this injury. It relieved pain, permitted change of posture, notably elevation of the head in bed, and was the best preventive of bed sores. The period of fixation varied from eight to twelve weeks or even longer. Sometimes the plaster was changed in six weeks for a shorter one. When the plaster was removed, massage and passive movements were of great value, but the only essential manipulation was to draw the limb outward to the extreme limit of abduction several times a day. Weight bearing should not be permitted until sufficient time had elapsed to permit firm union, confirmed, if possible, by *x*-ray pictures, nor until the essential movements at the hip were relatively free and under control.

Dr. F. J. Cotton of Boston, Mass. (by invitation), gave a lantern slide demonstration of the *x*-rays showing push and pull tests under treatment—artificial impaction with abduction. He believed that this abduction treatment was the proper method and the one that they should use after a very careful study of the method. He did not know exactly what the results were but there were certainly a great many of good ones, especially veracoxa cases occurring in adults. As Dr. Ochsner of Chicago had stated, there was no one method which would cure all of these cases. In a great many of these cases the impaction was not solid enough. During the past six years Dr. Cotton had had four cases of impaction, and in all of these the fractured part was entirely loose and was due to the trauma. The first *x*-ray pictures would not always tell one accurately what the condition absolutely was. They showed what happened in the pull up and the pull down when there was a fibrous union. They were saying that they obtained good results in these cases of fracture of the neck of the femur when, in fact, they were not good results. In these cases of abduction *per se* the question was how were they going to obviate the deformity. Many were now using this method, but it should not in his opinion be used as a routine method. In none of these cases should any routine method be used. Dr. Cotton said that he had been interested in the question of the unimpacted fractures of the neck of the femur, the cases that had been so successfully handled by the technique of Dr. Whitman. He had placed many of these cases in abduction, and they got well. With regard to the impacted fractures there was no doubt but that they were in the majority and there were only one or two things that should be done. One was to carry the limb well out and the other was to break up the impaction and keep the limb in proper position by means of a Buck's extension apparatus with the perineal sling. Abduction, particularly in elderly people with fracture of the neck of the femur and with a stiffened joint, played a great part. The abduction should be forced to the normal. Dr. Cotton showed some *x*-ray pictures bearing on this subject.

Dr. John B. Roberts of Philadelphia said they had been compelled to modify their methods of treating fractures, first those of the skull, radius, and humerus, and now those of the femur. Impaction was probably often green stick fracture, untorn periosteum, or entangled fragments. Non-union was probably often due to forcible and unwise tearing apart of fragments in order to make a diagnosis followed by inefficient coaptation or failure in maintaining coaptation. Hence there was a fear of setting the fracture lest handling break up impaction or partial fixation. This was admitted to be justifiable when the surgeon realized his inefficiency to get good results or for other reasons, as lack of efficient nursing or deficiency in the patient's curative processes. After reviewing the opinions of Scudder, Cotton, and Whitman in regard to the treatment of frac-

tures of the femur, the speaker said that the checking of abduction by the neck striking the upper rim of the acetabulum and the trochanter tissues striking the iliac tissues might not be the anatomical explanation but it seemed to him likely to be the correct explanation of the result achieved. As asserted, steadying of the replaced fragments might not be due to the tension of the capsule from abduction and traction and the altered direction of the iliopsoas muscle and the other muscles by full abduction might not lessen their tendency to displace the fragments but it seemed to him probably the correct theory. Whitman believed that "impaction" might be partial fracture and that abduction to reduce deformity and to secure fixation was not breaking up impaction. The retention of some control over the limb passed for impaction; it might be only entanglement, or preservation of the periosteum without tearing, or, in the young, "green stick" break, or some contact of the fragments as in diastasis. Whitman believed that loss of the femoral angle on which abduction depended was of great importance and that abduction to restore the femoral angle was not breaking up impaction necessarily, but that it restored the anatomical relations of the fragments in complete fractures and in those which were incomplete obtained apposition of the fragments. It corrected deformity and fixed the fragment in good position until union could occur. The shortening might be due to ascent of the trochanter without separation of the fragments. Dr. Roberts said it appeared to him to resemble the condition in classic fracture of the lower end of the radius which was so long misunderstood and which until this day caused that injury to be badly treated. To break up that impaction and entanglement was long considered unwise; hence, deformity, pain, and stiffness were the results for most patients sustaining the ordinary fracture of the radius near the wrist with backward displacement. Whitman believed that fixation of the apposed fragments by posterior support was absolutely essential; this was obtainable by a gypsum spica encasement of the leg, thigh, and pelvis up to the nipple line, holding the limb in a normal abduction. He also believed that the benefit of this method should be given to all ages if any local treatment was practicable in the case. He said that pain was relieved and that the patient could be moved without discomfort; bed-sores were not to be feared, and the head of the bed might be raised to relieve congestion of the lungs. Dr. Roberts believed that Dr. Whitman was right and was convinced that there was an analogy between this fracture and those of the shoulders, the wrist, and the elbow. The troubles came from imperfect anatomical reduction. After reduction, retention of apposition was not followed by such pain, discomfort, and functional loss as were formerly considered inherent in the injury. Whitman believed that skill and experience were needed at the outset in the application of the method, but there was compensation in that the surgeon controlled the situation at the start and need not depend on the extraneous aid of nurses and assistants week after week as was essential in the usual traction methods. Moreover, there was the stimulation of hope and belief in a good prognosis in the mind of patient and surgeon. Whitman believed that especially in transverse fractures union proceeded very slowly and from the interior of the bone rather than by external callus; hence accuracy of adjustment was essential and the weak part must be long supported. Weight bearing should be postponed for at least six months and not permitted until freedom of motion and muscular control showed that repair was complete. A modified hip splint that would permit motion without weight bearing was useful as an adjunct in treatment. The abduction method should be tried, as Whitman said, because it was an attempt to deserve success by trying for more ideal results than those with which they had been satisfied heretofore. The speaker believed that the method was based on true surgical principles, and that when it was checked by the *x*-ray before, during, and after its adaptation to the patient it was satisfactory in many cases. Open operation might be demanded when fragments were so displaced as to be irreducible by ordinary manipulations or when it was necessary to freshen and appose the fragments when non-union had occurred. There might also be cases where one would hesitate to employ this method because of danger from the ether or other causes.

Dr. John B. Walker said that a number of years ago he had his attention called to Dr. Whitman's treatment of fractures of the neck of the femur and five years ago he made a study of 100 of these cases at Bellevue Hospital and his findings corresponded with those of Scudder and Whitman. A great deal had been said regarding the giving of anesthetics to these patients but he thought that reduction could be made with the employment of any anesthetic. The reduction was made much easier when some form of traction apparatus was used. He was sure that there were many cases of unimpacted fracture of the neck of the femur admitted to the hospital in which the results were very unsatisfactory. An *x*-ray taken twenty-four hours later often showed the fragments to be in poor position. During the past year Dr. Walker had seen five cases where the radiogram taken six months after the injury showed that there was non-union. Out of about 116 cases examined, 40 per cent. were under 55 years of age. Dr. Walker had had three cases under fifteen years of age and five cases under 25 years of age. He now had a patient 65 years old who weighed 170 pounds; he came to the hospital with a fracture of the neck of the femur and a traction apparatus was applied without the use of any anesthetic. He was confident that at Bellevue Hospital the use of the Whitman method gave good results. In his cases there had been no mortality. Dr. Walker referred to a paper on "Operative Treatment of Fractures," which he had read before the American Surgical Association in 1912, in which he hoped that an increasing number of members would become more interested in developing the operative treatment for selected cases of fractures. Two weeks later at a meeting of the American Medical Association Mr. Lane presented a paper upon the same subject. These papers brought out very little discussion, the general sentiment prevailing that the average results after fracture were satisfactory and that operations were unnecessary. In 1911, at Denver, President Harte called especial attention to this subject and stated his belief that careful observation of the end results after fracture justified the conclusion that these results were not as satisfactory as was generally believed, and that members of the profession were not fully utilizing all the advantages in their power to secure the best results in fractures; therefore he advised the operative treatment for selected cases, especially in fractures of the femur. In 1912 the literature was full of references to operations. During the last two years surgeons had become convinced that the results must be improved. In fractures, the rapidity of union was proportional to the accuracy of reduction and the retention of fragments; delayed union was very largely due to faulty adjustment. Plating the fragments did not increase the nutrition, but it brought the fragments into early intimate contact. As their experience grew they would be able to select, after a study of the *x*-ray plates, those cases in which operation was indicated.

---

### Philadelphia Neurological Society.

At a stated meeting held January 24 Dr. Alfred Gordon presented "A Case with Cerebellar Symptoms." The patient was a man, about thirty-five years old, who, following an illness thought to be paratyphoid fever, presented tremor in the right upper and then in the right lower extremity, followed later by the same phenomenon on the left side. After a time ataxia was observed in the extremities, with a tendency to double up toward the right and to fall in the same direction. There was complaint of headache, with beginning optic atrophy in each eye. The reflexes were preserved.

Drs. C. W. Burr and G. B. Crow presented "A Man Showing Mirror Writing and Curious Associated Movements Without Palsy." The patient was a sailor in the navy about twenty-two years old who, after difficult birth, was thought to present some want of power in the use of both hands only. As time went on, it was found that movements performed with either hand were almost exactly duplicated by the opposite member. There was no peculiarity in the use of the lower extremities. The patient was ambidextrous, and in writing, normally with the right hand, he had learned to use also his left hand simultaneously for the same purpose, but with this, writing in mirror fashion. He could also write alone with the left hand, but always in mirror fashion only. There was no wasting or deformity, no palsy or sensory disturbance, the reflexes were preserved, the lower extremities were unaffected and intelligence was normal. The disorder was thought to be due to a cerebral anomaly in consequence of which movements of the hands on both sides of the body were controlled in equal degree by impulses from each side of the brain.

Dr. Wm. G. Spiller exhibited "A Case of Friedreich's Ataxia." The patient was a young man about nineteen years old, who from an early period of life had exhibited weakness in the lower extremities, with ataxia, but with exaggerated knee-jerks. In order to bring out the knee-jerks the patient sat with the thighs and legs considerably separated and the soles of the feet upon the floor, but making pressure on the ball of the foot, and at the same

time invoking reinforcement by means of movements in the hands. The gait was ataxic and there was slight incoordination of movement in the upper extremities. Also there was some want of control of the bladder, an unusual symptom in this disease. There was no history of syphilis.

Drs. G. L. Howell and S. D. W. Ludlum presented a communication entitled "Blood-pressure in Nervous Affections." They reported a number of cases in which observation showed that failure of the blood-pressure to rise with change from the recumbent to the erect posture was indicative of an atonic state and of a failure on the part of the patient to improve. Also this sign was used as a guide in treatment, as it was found that more physical activity could be undertaken in proportion as the blood-pressure rose with the change in posture.

Dr. J. H. W. Rhein delivered "The Presidential Address," in the course of which he discussed the relations of the neurologist to mental disease. He pointed out the need for psychopathic institutes in which diseases of the mind could be studied clinically along modern lines and anatomical studies and original investigation carried on, with the hope of shedding light upon the causes and mechanism of insanity, especially with a view to its prevention and cure.

The following officers were elected for the ensuing year: *President*, Dr. George E. Price; *Secretary*, Dr. Samuel Leopold; *Treasurer*, Dr. S. D. W. Ludlum.

---

Pathological Society of Philadelphia.

At a stated meeting held January 23 Dr. John Reichel and Dr. M. J. Harkins presented a communication entitled "Peptotoxin Production by the Bacillus of Contagious Abortion of Cattle." By treating animals with cultures of the bacillus of contagious abortion grown in beef broth to which peptone was added they succeeded in inducing a condition of hypersensitiveness or anaphylaxis.

Dr. Arthur H. Hopkins reported "Two Instances of Chronic Family Jaundice." In each of the families there were several individuals who from early life presented a varying degree of icterus, with occasional exacerbations, without signs of biliary obstruction, but with evidences of diminished resistance on the part of the red corpuscles of the blood.

Dr. Penn Gaskell Skillern, Jr., presented a communication entitled "Syphilis in the Etiology of Osteitis Fibrosa." He reported a case of this disorder in a girl at about the age of puberty in whom, in addition to the usual signs, a positive reaction to the Wassermann test was present. Improvement took place under treatment with mercury and iodide. In cases studied histologically the lesions resemble those induced by syphilis. Accordingly, Dr. Skillern formulated the conclusion that fibrous osteitis is a form of late hereditary syphilis.

# State Medical Licensing Boards.

## STATE MEDICAL EXAMINATION QUESTIONS.

Arkansas State Medical Board.

*May 14 and 15, 1912.*

*(Continued from page 275.)*

BACTERIOLOGY.

1. Give the morphology of bacteria.
2. State briefly a method for obtaining a pure culture.
3. What is the difference between active and passive immunity? Give example of each.
4. What are the protective agencies by which the body protects itself against the harmful effects of pathogenic bacteria?
5. What is the difference between an antitoxin and a bacterial vaccine?
6. What are opsonins and what do you understand by the opsonic index?
7. Describe the *Bacillus typhosus* and state briefly how you would differentiate it from the *Bacillus coli communis*.
8. Describe in detail the process of finding tubercle bacilli in urine.
9. In what disease may the pneumococcus be the etiologic factor?
10. Differentiate between the gonococcus and the *Diplococcus intracellularis meningitidis*.

THEORY AND PRACTICE OF MEDICINE.

1. What complication is likely to appear in the last part of the second week and all of the third week of typhoid fever?
2. Give (a) physical signs of pneumonia; (b) treatment for first stage of lobar penumonia.
3. (a) At what age do patients usually suffer from catarrhal stomatitis? (b) Give treatment.
4. Give etiology and treatment of acute gonorrhea.
5. Give cause and treatment of epidemic cerebrospinal meningitis, carefully giving detailed technic of treatment.
6. Outline the normal liver dulness.
7. Give diagnosis and treatment of measles.
8. (a) Give the causes of malaria. (b) Name two forms of malarial fever and give the varieties of organisms found in each form. (c) Give treatment for estivo-autumnal form of malarial fever.
9. Give causes, diagnosis, and treatment of rickets.
10. What would you do for pulmonary hemorrhage occurring in the course of tuberculosis?

OBSTETRICS.

1. How would you determine the death of a fetus *in utero?*
2. Define abortion, miscarriage, premature labor.
3. Name possible sources of puerperal hemorrhages and treatment of each.
4. Define menstruation; age at which it appears; the name given to this period of woman's life; the age at which it ceases.
5. Give the normal duration of pregnancy. Give limit of duration from a medicolegal standpoint.
6. How frequently must you examine the urine during pregnancy? To what particular normal or abnormal constituents would you pay attention in this urinary examination? In the presence of general edema with albumin and casts in urine, which increased in spite of proper treatment, what symptom would lead you to bring on artificial labor?
7. What would lead you to suspect extra-uterine pregnancy?
8. How would you determine that a dead infant had been born alive?
9. In breech presentations describe the different methods of delivering the after-coming head.
10. What are the dangers of traction on the child and placenta?

---

## ANSWERS.

BACTERIOLOGY.

1. *According to form, bacteria may be classified* as: (1) *Cocci*, which are round or oval, and may appear singly, in pairs, in chains, or in groups; example—streptococcus of erysipelas. (2) *Bacilli*, which are rod shaped, with the longer sides parallel and the short ends either straight, rounded, or concave; example—bacillus of tetanus. (3) *Spirilla*, which are spiral; example—spirillum of relapsing fever.

2. *To make a pure culture:* "All that is necessary is to inoculate the liquefied gelatin with the mixture of bacteria, and after thorough agitation so as to separate each cell from its neighbor, to pour the liquid on to the surface of a sterile plate. The gelatin now solidifies and imprisons, as it were, the separated cells. Each of these now multiplies and reproduces its kind; eventually, in the course of a day or two, a small growth, perhaps of the size of a small pinhead, appears. This is called a colony, and since it is derived from a single cell it constitutes a pure culture. Such is the principle of the dilution method for obtaining pure cultures. The isolation once accomplished, all that is necessary is to transplant the colony to sterile culture media so as to keep up the growth." (*Reference Handbook of the Medical Sciences.*)

3. "*Active immunity* follows an attack of a certain disease and secures immunity for that alone, which may last but a short time (erysipelas, cholera) or for a longer period (typhoid), or even for life (variola); or it follows inoculation of a virus weaker than necessary to cause the typical disease (vaccination against smallpox); or it follows inoculation by bacterial products apart from the organisms themselves.

"*Passive immunity* is the term applied to the effect of a serum derived from an immunized animal and injected into one not immune, the theory being that in the blood of the former there is a chemical substance (antitoxin) which neutralizes the toxin in the donating animal, or otherwise it would show symptoms, and by borrowing its serum for the infected animal the toxin is opposed by the

alien antitoxin."—*Example:* Diphtheria. (From Thayer's *Pathology.)*

4. *Protective agencies against pathogenic bacteria* are: The acidity of the gastric juice, the urine, and the vaginal secretion; the bactericidal action of the blood and lymph; the action of the leucocytes and phagocytes; the alkalinity of the blood; and the agglutinating action of the blood.

5. *Difference between an antitoxin and a bacterial vaccine:* "The antitoxic sera act directly upon the poison secreted by the living bacterial cell and neutralize its toxic property, while the bacteriolytic sera affect the bacteria themselves and destroy them or paralyze their action. Since the antibacterial sera are without effect upon the formed toxin, they are mainly useful in practice as a means of protecting against the bacterial invasion, while the antitoxic sera (*e.g.* diphtheria) may be employed to combat an infection already in progress. Broadly speaking, the latter are curative, the former protective." (Jordan's *Bacteriology.*)

6. *Opsonin* is that quality of a serum which makes a microorganism more susceptible to phagocytosis.

The *opsonic index* is the relative amount of opsonins in a serum, as compared with the normal standard. It is obtained by dividing the average number of bacteria taken up by a leucocyte under the influence of a given serum by the average number taken up by a leucocyte under the influence of a standard normal serum.

7. *Bacillus typhosus* is a rod-shaped organism, with rounded ends, is from 2 to 4 microns in length and about three-fourths of a micron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aërobic and facultative anaërobic, and is motile.

*To distinguish the typhoid bacillus from the colon bacillus:* (1) On gelatin plates, the colonies of typhoid develop more slowly than those of colon bacillus. (2) The colon bacillus causes fermentation with production of gas in media, which contain sugar; the typhoid bacillus does not. (3) The colon bacillus produces a strong acid reaction and coagulates milk within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk. (4) In peptone solution the colon bacillus produces indol; the typhoid bacillus does not. (5) The typhoid bacillus gives the Widal reaction with typhoid serum; the colon bacillus does not.

8. *To find tubercle bacilli in the urine:* The urine should be drawn by a catheter, with the utmost regard to cleanliness and asepsis (so as to exclude the smegma bacillus). The urine thus obtained must be centrifuged for a long time. Some of the sediment is placed on a slide with a small quantity of egg albumin; it is covered with some carbolfuchsin, and allowed to steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin, red rods, while all other bacteria will appear blue.

9. The *pneumococcus* may be the etiological factor of lobar pneumonia, pleurisy, pericarditis, endocarditis, meningitis, enteritis, and conjunctivitis.

10. The *gonococcus* does not usually grow on the ordinary culture media, whereas the *Diplococcus intracellularis meningitidis* usually does.

### THEORY AND PRACTICE OF MEDICINE.

1. Perforation of the intestine.

2. *Physical signs of lobar pneumonia: "Inspection* reveals during the first stage deficient movement of the affected side, due to pain. The apex-beat is normal in situation, and the interspaces do not bulge. In the second stage the healthy side rises normally, the affected side lagging behind. If both lower lobes are impervious to air the diaphragm cannot descend and the epigastrium does not project during inspiration, the breathing being conducted by the upper part of the chest (superior costal respiration). *Palpation* during the first stage shows the vocal fremitus to be more distinct than normal, especially over the diseased portions. In the second stage the vocal fremitus is markedly exaggerated, except in those rare instances of occlusion of the bronchi by secretion. The cardiac impulse is felt in the normal position. *Percussion*: In the first stage the percussion note is slightly impaired at times, having a hollow or tympanitic quality. In the second stage there is dullness over the affected parts, with an increased sense of resistance. Over unaffected adjoining areas the resonance is increased (Skoda's resonance).

*Auscultation.*—In the first stage there is heard over the affected part a feeble vesicular murmur, associated with the true vesicular or crepitant (crackling) râle, heard at the end of inspiration only. In the second stage there is harsh, high-pitched, bronchial respiration, at times resembling a to and fro metallic sound, except in those rare instances in which the bronchi are more or less filled with secretion. Bronchophony, or distinctly transmitted voice, is present and at times pectoriloquy, or distinct transmission of articulated sounds, may be heard. In the third stage the breathing changes from bronchial to bronchovesicular and the crepitant râle (crepitation redux) returns. As resolution proceeds the breath sounds are associated with large and small moist and bubbling râles." (Hughes' *Practice of Medicine.*)

*Treatment:* There is no routine treatment. The patient should be put to bed in a well-ventilated room; milk diet, and fractional doses of calomel followed by a saline should be administered. Symptoms are treated as they arise.

3. *Catarrhal stomatitis* is most common during infancy and childhood. Treatment consists in the removal of the cause, attention to the diet, and cleanliness of the mouth. The mouth should be washed out with cold water, or Dobell's solution, or a solution of boric acid or borax. In severe cases a solution of silver nitrate (two to five grains to the ounce) may be necessary.

4. *Gonorrhœa* is caused by infection with the *Diplococcus gonorrhœæ.*

*Treatment:* Support the penis and testicles with a bandage; avoid violent exercise, alcoholics, and all sexual excitement; drink plenty of water; avoid spicy foods; urethral irrigation of hot corrosive sublimate solution, 1:20,000, or of warm potassium permanganate solution, 1:4,000.

5. Epidemic cerebrospinal meningitis is caused by the *Diplococcus intracellularis meningitidis.* Treatment consists of rest in bed and the administration of anti-meningitic serum; for details of this latter, see THERAPEUTICS, question 10. Liquid but nourishing diet is necessary; and cold compresses may be applied to the head and spine.

6. The outlines of liver dullness are shown in Hutchinson and Rainey's table:

| | | Middle Line | Mammillary Line | Midaxillary Line | Scapular Line |
|---|---|---|---|---|---|
| Upper limit.. | Deep dullness | ..... | Fourth space | Seventh space | Ninth space |
| | Superficial dullness | Blends with heart dullness | Sixth rib | Eighth rib | Tenth rib |
| Lower limit..... | | Hand's breadth below base of xiphoid | Costal margin or somewhat above or below it | Tenth space | Blends with kidney dullness |

7. Measles is diagnosed by its gradual onset, nasal catarrh, Koplik's spots, papular eruption on fourth day, and branny desquamation. *Treatment* consists in rest in bed, isolation, protection from bright light, a diaphoretic and mild laxative, cold sponging, and inunction with vaseline; tonics are required during convalescence.

8. Malaria is caused by the *Plasmodium malariæ.* The tertian variety is caused by the *Plasmodium vivax,* and the estivoautumnal variety by the *Plasmodium præcox. Treatment of the estivoautumnal variety* demands rest in bed, and the administration of quinine sulphate (5 grains every 4 hours for a week); this is then reduced to about 2 grain doses for several weeks. Mosquitos must be exterminated or kept out of the house.

9. *Rickets* is a disease of young children characterized by nutritional changes, deformities of the bones, weakness of the muscles and ligaments, and various nervous disorders. Heredity, faulty hygiene, and improper feeding are etiological factors of importance.

*Symptoms:* The early symptoms may be very mild, but in severe cases restless sleep, profuse sweating of the head, digestive and nervous disturbances, and perhaps slight fever are present. The bones soften and enlarge at their articulations. Dentition is delayed and the fontanels remain open. The appetite is capricious, constipation is marked and may alternate with diarrhea, and the abdomen is enlarged and tympanitic. The affection predisposes to

inflammation of the various mucous membranes, and various deformities are liable to result from the changes in the bones. The course of the disease is chronic, although marked improvement takes place after proper treatment has been instituted.

*Treatment* consists largely of fresh air, sunlight, daily bathing and proper feeding. Cod-liver oil (gtt. 10 to 3i), syrup of the lactophosphate of lime (3½), syrup of the iodide of iron (gtt., 2), and similar remedies may be administered. Sweating may be controlled by atropine (gr. 1/800-1/200). Small doses of calomel and soda are beneficial in gastrointestinal disturbances. Deformities may be prevented by postural methods, friction, massage, and the avoidance of exertion. (Pocket *Cyclopedia.*)

10. *Pulmonary hemorrhage in tuberculosis.* "If there is more than a mere trace of blood in the sputum the patient should be put to bed and given cracked ice, which is to be allowed to melt slowly in the mouth from time to time. According to the severity of the case some or all of the following measures are to be adopted: An ice-bag may be applied to the precordium, and kept on constantly especially if there is an elevation of temperature. Tincture of aconite may be given in sufficient dosage to quiet the heart and to reduce and keep the pulse-rate to 60 a minute. Crystallized calcium chloride may be given in solution in doses of 15 grains every second hour, for about 4 days; it is then to be intermitted for 4 days or more, and used again, if need be. In the interval lead acetate, in doses not exceeding 5 grains, thrice daily for 3 days, may be given, to be followed for 2 days by aromatic sulphuric acid in doses of 30 drops, well diluted, thrice daily or oftener. Hydrastinin hydrochloride in doses of 1/24 to ⅛ grain hourly or less often is sometimes useful. Among drugs to be recommended are also the turpentine group, of which erigeron is among the best. Codeine may be given by the mouth in doses of from ⅛ to ½ grain every second hour or less often; or morphine acetate may be given by the mouth in doses of ⅛ grain every hour or two; or morphine sulphate hypodermically in dose sufficient to prevent coughing absolutely in severe cases. Atropine sulphate, from 1/2000 to 1/60 grain, may be given hypodermically at the beginning of the attack, and will often cut it short. The patient must be forbidden to speak, except in a labial whisper. Cold liquid food should be given in small quantities at intervals of about 2 hours. The bowels should be moved daily, without straining, by enema, glycerin suppository, or saline purge, as necessary. (Gould and Pyle's *Cyclopedia.*)

OBSTETRICS.

1. Symptoms of death of fetus are: cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements are absent, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time, crepitus of its cranial bones may be elicited.

2. *Abortion* is delivery of the product of conception before the twelfth week.

*Miscarriage* is delivery of the product of conception between the twelfth and twenty-eighth weeks.

*Premature birth* is delivery of the fetus between the twenty-eighth week and full term.

3. *Hemorrhages of the puerperium:* Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

The treatment in general consists, first of all, in removing the cause.

"In the presence of actual hemorrhage the treatment varies according as the placenta is still within the uterus or has already been expelled. In the former case the uterus should at once be grasped through the abdominal wall and firmly kneaded. If firm contractions come on, all is well, but if the hemorrhage continues and the uterus relaxes as soon as the kneading is stopped, the placenta should be expressed by Credé's method; and if this cannot be accomplished and the patient's condition is alarming, manual removal may become necessary. . . . If the hemorrhage does not cease after the delivery of the placenta, the cause should be ascertained and suitable treatment instituted. Tears should be located and their edges brought together by sutures. On the other hand, if the hemorrhage is the result of the retention of placental tissue, the carefully disinfected hand should be carried up into the uterus in order to seek for and remove the retained cotyledon. . . . After separating the retained portion of the placenta the hand should not be withdrawn at once, but should be allowed to recede gradually as it is forced down by the contraction of the fundus. If the hemorrhage is due to atony the uterus should be vigorously kneaded, and from forty to sixty minims of ergot or of ergotol administered hypodermically. . . . If these measures are not attended with the desired result, a very hot intrauterine douche of several liters of sterile salt solution should be employed. . . . If the hemorrhage persists in spite of the douche, our only hope of controlling it is by packing the uterus tightly with sterile gauze. Before resorting to the use of the pack it is always advisable to palpate the interior of the uterus, as occasionally a portion of the placenta may have been retained, even though immediately after expulsion the organ may have apparently been entire." (Williams' *Obstetrics.*)

4. *Menstruation* is a periodic disturbance in the female characterized by a bloody mucous discharge from the uterine cavity; it lasts during the period of a woman's sexual activity, but is temporarily suspended during pregnancy and early lactation. It usually appears between the 13th and 15th year, at the period of puberty; it usually ceases in woman about 45 years of age, but the period is quite variable.

5. The normal duration of pregnancy is about 280 days. In this country there are no legal limits to the duration of pregnancy. Each case must be taken on its own merits, and the result will probably depend upon many factors, such as (1) the special conditions in each case; (2) the ascertained truthfulness or untruthfulness of the woman and her layers and witnesses; and (3) the gullibility or otherwise of the jury.

6. In the early part of pregnancy the urine should be examined every month or six weeks; so long as everything is normal this will suffice. Later, the examination should be more frequent, say every two weeks. Particular attention should be paid to the quantity of urea excreted, and to the presence of albumin and casts. When there is a diminished output of urea, or when albumin and casts are present the examination should be made twice a week or oftener.

The induction of artificial labor would be indicated (when other treatment failed) in the presence of: Continued headache; tinnitus aurium; dizziness; digestive, visual, and nervous disturbances; vomiting; vertigo; and convulsions.

7. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterilty; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The *os uteri* is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Textbook of Obstetrics.*)

8. If respiration has taken place the lungs will float on being put into water; if respiration has not taken place the lungs will sink. Further, the lungs before respiration are situated at the back of the thorax and do not fill the cavity; whereas, after respiration has occurred they fill the whole cavity.

9. The different methods of delivering the after-coming head are: Compression of the fundus uteri; the Prague method (traction on feet and shoulders); Martin's method traction on the jaw, with external pressure in the suprapubic region); Smellie's method (traction on jaw and shoulders); and forceps.

10. *Traction on the child* may cause abrasions, contusions, laceration of the skin, depression of the cranial bones, or even fracture of the same, laceration of the blood-vessels, or possibly temporary facial paralysis from injury to facial nerve.

*Traction on the placenta* tends to pull the placenta flatwise (like a button in a buttonhole) and thus obstructs its egress; it also tends to cause inversion of the uterus, to tear the cord or placenta, and to leave portions of the placenta behind.

(*To be concluded.*)

### ADDITIONAL REMARKS ON CARDIOSPASM AND IDIOPATHIC DILATATION OF THE ESOPHAGUS.*

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

IDIOPATHIC dilatation of the esophagus or dilatation without real stenosis is usually the result of a long persisting and repeatedly recurring cardiospasm. The proof that the latter is the main cause of the dilatation of the esophagus is apparent by its successful treatment by stretching the cardia.

The diagnosis of cardiospasm is ordinarily easier if accompanied already by esophageal dilatation. For the latter produces more marked symptoms.

Cardiospasm is by no means a rare occurrence. It is, however, frequently overlooked, because the subjective symptoms are taken for hysterical phenomena. About two years ago I published a paper on a similar subject.†

This article deals with my new experiences in this class of cases. In looking over my record of the last two years (1911 and 1912) I find that I have treated during this period 37 new cases of benign cardiospasm, of which 12 were accompanied by marked dilatation of the esophagus.

In the following I intend to describe out of this group three cases of severe cardiospasm with esophageal dilatation, two on account of the difficulty they presented in diagnosis, and one on account of almost insurmountable obstacles of treatment. I shall then add two cases of cardiospasm of a malignant type, due to neoplasms of the stomach, which I observed during the year 1912.

CASE I.—Cardiospasm with moderate dilatation of the esophagus. Dr. W. W., age 44, had a severe attack of pneumonia in 1904. In 1907 he had typhoid fever, in 1908 blood poisoning due to a decayed tooth. In this attack he lost three teeth and part of the lower jaw bone. Patient is about 5 feet 5½ inches tall and in 1908 his weight was 118 pounds stripped. At this time a cough was noticed, especially when eating. The pupils of his eyes were dilated in various ways. For instance the right pupil might be dilated for a week or more and then become normal, while the left pupil became dilated.

Vision normal, 25/20 in each eye. Accommodation normal. No fundus changes—no oculist consulted could give an explanation. Eserine 2 per cent. solution was used to contract the pupil. In April, 1911, a diagnosis of the trouble was made by me. An *x*-ray picture taken. At this time cough was very frequent. Eye symptoms were present, one pupil always being larger than the other. In the morning the right pupil might be large, in the evening small, while the left was small in the morning and large at night. After severe coughing the pupils might be the same size for a moment. Sometimes, not often, food was vomited two or three hours after eating, no signs of digestion having taken place in the vomited matter. After treatment for 3 or 4 months increase of weight began. At the end of 9 months the patient had increased 20 pounds in weight.

At this time, January, 1913, the patient weighs more than ever before—138 pounds without clothes. Cough is present though not so frequent or severe. Eye symptoms about gone. Once in a while if tired one pupil gets larger than the other. The influence

FIG. 1.—Dr. W. W. showing dilatation of the esophagus.

of smoke or wind on the eye is very marked. For instance a ride in the wind in an auto without goggles will make the pupil small in one eye and large in the other.

If in a room where men are smoking the same result takes place, showing that the eyes are very sensitive to irritation. A short time ago the patient was laid up in bed for a few days with a cold. Carlsbad salts were used every morning. During these days there was no cough. When patient is well he takes salts every two weeks. If he takes the salts on Monday morning he has more cough on Monday due to the irritation. On Tuesday he will cough possibly two or three times during the entire

*Read before the Section on Practice of Medicine at the New York Academy of Medicine on Feb. 18, 1913.

†Max Einhorn: "Stretching of the Cardia in the Treatment of Cardiospasm and Idiopathic Dilatation of the Esophagus," *American Journal of the Medical Sciences*, October, 1910.

day. Wednesday he will cough more than Tuesday but not so much as if salts had not been taken. After salts are taken not very much mucus is expectorated; at other times quite a great deal during the entire day. Lungs and heart normal. In the morning about three hours after eating a very hard fit of coughing takes place. This is not so marked now (January 19, 1913) as a year ago. General health fine, bowels always very regular.

April 25, 1911. Swallowing sound absent. Bougie 43 F. passes cardia and enters stomach. Dullness at the right manubrium sterni. Radiograph of esophagus (Fig. 1) taken by Dr. L. G. Cole confirms the diagnosis.

Case II.—Cardiospasm with moderate dilatation of the esophagus. December 17, 1912. John H., 31 years old, clerk, has always been well until seven months ago. He then had "gas on the chest," and toward the end of March food started to disagree with him. The rolls in the morning used to come up in his mouth. He had no pains. In July he had a hemorrhage. He did not, however, vomit the blood, but it simply welled up into his mouth. There was then a little pain on pressure in the chest over the sternum. Never had pain two or three hours after meals, nor immediately after eating. Bowels are somewhat constipated and need artificial help. He never had difficulty in swallowing. After this hemorrhage he would vomit every two or three days. He had been on a milk and egg diet for two months. He would raise considerable mucus while eating and right after. In March, 1912, he weighed 135 pounds. He has complained of pressure in the chest at night. Sometimes he would have to leave the table in order to vomit; at other times this would not occur. At times even liquid food could not be ingested. Patient would raise mucus. December 2 he weighed 118 pounds; on December 23 he weighed 132 pounds.

Case III.—September 23, 1911. Impermeable cardiospasm. Miss Jennie B., 27 years old, teacher.

Fig. 2.—Miss Jennie B. Showing dilatation of the esophagus.

Family and previous history unimportant. When she was about 16 years old she had the sensation as though her food was too dry. There was a choking feeling in her throat. She also suffered from nervous prostration. When she was 17 years old she began to vomit her food, but until the food came up she would choke violently. She never had to put her finger into her mouth to produce vomiting. Whenever she took any food she would always feel a fullness and a pressure in the thorax. If after taking food or water she would take a deep breath, set her chest muscles and compress the thorax, it felt to her as though the entrance to the stomach suddenly opened and she would immediately be relieved of the choking sensation. She coughed a great deal at night, particularly after partaking of a large supper. During her sleep chyme would run out of her mouth upon the pillow. Bowels were always constipated. During the last three years she lost about 36 pounds. Whenever she had any nervous strain her trouble would always be worse. She never had nausea; the food was simply regurgitated into the mouth and she ejected it.

Fig. 3.—Caspar G. Showing a dilated esophagus.

September 14, 1911, swallowing sound absent. Bougie (43 F.) engages at 16 inches at the esophageal wall. It does not enter the stomach. But on pushing drags the wall downward. A radiograph of the esophagus (Fig. 2), taken by Dr. L. G. Cole, corroborates the diagnosis of dilatation of esophagus.

September 25, 1911, the duodenal olive (17 F.) has entered the duodenum. December 26-28, the cardia was stretched by means of the pyloric dilator. January 12, 1912, this method of stretching the cardia backwards from the stomach was demonstrated on the patient at the Clinical Society of the German Hospital. During January, February, and March, 1912, the patient's cardia was stretched with the pyloric dilator. We succeeded in pulling up size 52 F. and patient was markedly better. She could partake of ordinary meals. She soon gained about fifteen pounds in weight.

*Cardiospasm Caused by Malignant Growths of the Stomach.*—Case IV.—November 2, 1912. Caspar G., 50 years old, began to be troubled with a difficulty in eating about four months ago. At first

the patient noticed that in taking solid food he would require some liquid, in order to make it go down. Later on this maneuver did not help, and the patient had to subsist on liquid food. Ultimately even this would cause immediate regurgitation. The patient was able to retain barely a few tablespoonsful of milk, suffering great discomfort in his chest even then. During the four months of illness the patient had lost about twenty pounds. The examination showed thoracic organs apparently normal. Nothing could be discovered in the patient by palpation in the abdomen.

Esophagus.—Swallowing sound absent at the ensiform process. Bougie 43 F. enters the esophagus up to 19 inches from the teeth, where an elastic resistance is felt. Whether the latter was caused by a deep-seated esophageal sacculation, or by the stomach wall, was difficult to decide. The blood showed a moderate leucocytosis.

The short history spoke against an idopathic dilatation of the esophagus due to cardiospasm, and pointed rather to a malignant neoplasm. The *x*-ray picture of the esophagus (taken by Dr. W. H. Stewart at the German Hospital) showed marked dilatation of this organ and no constriction at cardia (Fig. 3). In as far as the patient was unable to partake of even small quantities of fluid a gastric fistula had to be established. At the operation performed by Dr. Willy Meyer a thorough exploration showed the cardia and pylorus free from any growth, while a malignant tumor was found at the lesser curvature of the stomach.

The symptoms of dysphagia were therefore due to a spasm of the cardia due to a growth in the vicinity.

Case V.—November 23, 1912. Mrs. Yetta M., aged 28, complains for the last six months of a feeling as if food stopped before reaching the stomach; choking sensation after swallowing, and

Fig. 4.—Mrs. Y. M. Showing the position of a growth in the stomach.

regurgitation of food. Vomits immediately after eating, especially after partaking of meats and heavy foods. Frequently vomits after drinking water, especially if cold. Rarely vomits at night, and then only mucus and water. Rarely vomits after breakfast, but nearly always after luncheon and dinner. Has considerable pain under sternum on swallowing. At present she is only able to eat eggs, occasionally a cracker, milk, and soups; of the latter only small quantities. The patient has lost about thirty pounds in weight.

Present condition.—Physical examination of the chest does not reveal anything abnormal. Palpation of the abdomen shows an oval mass of walnut size to the left of the ensiform process, situated under the margin of the left costal arch. Swallowing sound is absent at the ensiform process. Bougies 48-54 enter the stomach, a slight resistance being felt at cardia and easily overcome. Wassermann's test was negative.

Notwithstanding that the cardia was not stenosed, severe dysphagia existed. The latter must be ascribed to cardiospasm caused by the growth in the lesser curvature of the stomach. The radiograph taken by Dr. Holding corroborates this diagnosis (Fig. 4). The patient was treated by me at the Postgraduate Hospital. She refused any operative intervention.

*Remarks.*—Case I (W. W.) illustrates that coughing spells may be caused by dysphagia due to cardiospasm. This patient, in fact, complained of nothing else but his cough during or immediately after eating, and he came to me merely for this affliction. Patient, who is a distinguished eye specialist, made observations with regard to his pupils, which seemed to be affected reflexly from the anomaly at the cardia. The description of these phenomena were given in his own words.

Case II (John H.) came with the diagnosis of gastric ulcer. His short report consisted in the statement that he suffered from indigestion since February, 1912; in June he had a hemorrhage from the stomach (vomiting of a cupful of blood). He was treated with rectal feeding and then with the regular Leube rest treatment, but without much improvement. Notwithstanding the liquid diet in which he persisted all along, and of which he took but sparingly, he continued to suffer and lose. The diagnosis of gastric ulcer appeared certain, and it was left to me merely to map out a plan of treatment. Before doing this I wished to ascertain, if possible, the localization of the ulcer, and gave patient the duodenal bucket. The next morning it was found that the bucket did not enter the stomach. It had remained over night in the esophagus. This indicated that there was an abnormal condition present within the esophagus. A further examination showed that the swallowing sound was absent. A bougie (43 F.) met with a slight resistance at 12½ inches, and again at 17 inches from the lips, which both were easily overcome after waiting a few seconds and pushing the instrument downwards. Bougie 48 F. showed a very similar state of affairs. The diagnosis of esophageal spasm and cardiospasm was now easily made. The case shows how important it is to enter into the details of the symptoms and to examine the neighboring organs in instances in which the picture of the disease is either not fully clear or its cause obscure.

Case III (Miss Jennie B.) serves as a good example of an impermeable cardiospasm. A bougie always failed to enter the stomach, the end regularly becoming engaged in the sacculation of the dilated esophagus. An attempt to introduce a dilat-

ing catheter over the thread of a duodenal olive failed, the former being caught in the same sacculation. The pyloric dilator was given to patient during the afternoon, and left in the digestive tract until the following morning. It was found that the end had reached either the duodenum or the stomach. After inflating the balloon we succeeded in stretching the cardia backwards from the stomach. This method was demonstrated on patient at the Clinical Society of the German Hospital on January 12, 1912. The patient then rapidly improved. The pyloric dilator will thus be found of practical utility in some cases of impermeable cardiospasm.

Cases IV and V show that cardiospasm may at times be encountered associated with, or more correctly due to, a malignant neoplasm of the stomach. In case IV the cardiospasm was accompanied by dilatation of the esophagus, as the radiograph well shows. In case V, which is very similar to case IV, esophageal dilatation is likewise present, though not so pronounced. (See Fig. 4.) Here a small nodular tumor could be detected by palpation, while in IV the physical signs with regard to a tumor were absolutely negative. In both the diagnosis of malignancy was made, in four principally by the symptoms (gradually increasing dysphagia for a period of four or five months, with loss in flesh and no cessation in the ailment), and in V by the same symptoms in association with the result of palpation. In IV the diagnosis was verified by the *autopsia in vivo* at the operation, and in V by the further growth of the tumor.

The treatment of this malignant form of cardiospasm will be quite different from that of the benign form. It will consist in an operation for the removal of the growth, and if this be impossible, in the establishment of a gastric fistula. Forcible stretching of the cardia is here too dangerous, and therefore inadvisable.

Before concluding I may be permitted to emphasize a few points with regard to diagnosis and treatment of cardiospasm.

The symptomatology and diagnosis of cardiospasm and idopathic dilatation of the esophagus are well known, and have been also briefly described in my previous paper. Here I wish to lay stress on the great importance of Meltzer's swallowing sound. If it is found present either at once or seven seconds after deglutition, there is neither cardiospasm nor idiopathic dilatation of the esophagus present. If it be considerably delayed twelve to twenty seconds after swallowing of water, or if it be now delayed and now absent, cardiospasm is frequently present. Again, if it is always absent, and bougies (43-48) enter the stomach there is as a rule idiopathic dilatation of the esophagus. Radiographs will be able to confirm the diagnosis and must be considered of great assistance.

As regards treatment cases of mild cardiospasm quickly improve under the influence of a nerve sedative also after the passing of a somewhat larger bougie (43-54 F.) through the cardia into the stomach. In severer cases of cardiospasm, and in all instances of idiopathic dilatation of the esophagus, the forcible stretching of the cardia by means of a cardiodilator (up to size 8-10 cm. circumference) is essential. Acording to my new experiences, the forcible stretching of the cardia gives such excellent results that I consider it a sovereign remedy for cardiospasm and primary dilatation of the esophagus.

# TIBIAL BONE TRANSPLANTATION IN THE POSTOPERATIVE MASTOID WOUND.

By MILTON J. BALLIN, M.D.,

NEW YORK.

ADJUNCT OTOLOGIST, MT. SINAI HOSPITAL.

Since the introduction of operative procedures on the mastoid bone, surgeons have endeavored to devise methods by which the mastoid wound would heal more rapidly and would be associated with as little deformity as possible. In all these surgical measures it has been the aim to eradicate all the diseased tissue as thoroughly as possible, in order to permit the development of healthy granulation tissue, and eventually to bring about complete closure of the wound.

This process of repair does not progress the same in all cases. It varies in accordance with the size of the mastoid cavity and the pathological changes in the middle ear and external auditory canal at the time of the operation, and is also influenced by the age and constitutional condition of the individual. As a rule one may expect closure of the wound in from four to six weeks, although some cases may remain open for months. Even at best, healing of the mastoid cavity is slow and tedious.

The usual open method of packing and repacking every third or fourth day until complete recovery is in itself more or less painful, and frequently taxes the patience, not only of the individual, who may be of a very nervous temperament, but also of the attending surgeon.

In order to hasten the early or primary closure of the mastoid wound, to avoid the packing and repacking, and to obtain a better result cosmetically, various methods have been suggested from time to time.

The following may be mentioned as some of the more important: (1) Blake's blood clot method;[1] (2) the serum method devised by Stuart-Low;[2] (3) filling the wound with vaseline dressings (Roy);[3] (4) filling the cavity with bismuth paste as suggested by Beck;[4] (5) soap emulsion dressings; (6) picric acid dressing (Bondy);[5] (7) treatment without packing (Mühlen, Zarniko);[6] (8) filling the healthy granulating wound some days after the primary operation with melted sterile paraffin (Politzer's method);[7] (9) Gruber's method of secondary suture of the wound;[8] (10) Bondy's secondary blood clot method recently revived by Held of New York; (11) filling the wound with glutol (Kretchman) and with Mosetig bone (Biehl); (12) periosteal flaps after the mastoid operation.[9]

These have been used with varying success by otologists of to-day and do in many instances give very satisfactory results. The above, as well as the method of bone transplantation as suggested by me, are used in the acute cases of mastoiditis.

Having been interested for some time in bone transplantation and having observed the splendid results obtained by the general surgeon by this method of treatment, and in particular by the results of Dr. A. A. Berg, who read an excellent paper on this subject at one of the meetings of the New York Academy of Medicine last winter, I conceived the idea that the same procedure might be applicable to the vascular mastoid bone. I did not know at the time whether transplantation of bone would be feasible here, but thought I would give it a trial when the opportunity presented itself.

I was intensely gratified to see this belief substantiated by a most excellent result, and made a brief report of the case in the August number of the *American Journal of Surgery* as being the first instance in which a bone graft had been used in a postoperative mastoid wound. The case in question was as follows:

Case I.—A young man, H. R., aged 31 years, was admitted into the otological service of Mount Sinai Hospital on Thursday, June 27, 1912. Six weeks prior to his admission into the hospital he had an attack of influenza, which was followed by an acute otitis media in the right ear. The drum ruptured spontaneously and was followed by a profuse purulent discharge. The patient noticed a swelling behind the ear which was of three weeks' duration, so that when I saw him he had all the evidences of an acute mastoiditis. I therefore deemed it advisable to open his mastoid, and two days after admission, June 29, I performed the ordinary Schwartze-Stacke operation. Having removed all the diseased tissue as thoroughly as possible, I packed the wound in the usual way. Five days later I removed the dressing and found a clean granulating wound, with only a slight seromucous discharge. Two days later, July 6, in other words, one week after the primary operation, I decided to do a bone transplantation. The patient was again anesthetized and, taking a proportionately sized piece of bones with its periosteum attached from the crest of the patient's tibia, I cut it so as to fit into the open mastoid cavity. The section of bone was rectangular in shape and measured an eighth of an inch in thickness, half an inch wide and two inches in length. The raw edges were slightly beveled so as to lie in close contact with the granulating surfaces of the mastoid cavity. The skin was then completely sutured, with the exception of a small opening in the inferior angle, in which I placed a small gutta-percha drain. As there was no reaction, I allowed the patient to get out of bed two days later, but did not disturb the dressing until the following day. Finding merely a slight mucous discharge, I removed the drain and allowed the opening to close, so that I had a perfect primary union on the tenth day after the original mastoid operation. I kept the patient in the hospital for three weeks in order to observe the course of the wound; as there was no reaction, I considered the case cured. I have had him under observation since July, seeing him from time to time. It is now a period of six months from the time of the operation. The transplanted bone has been retained and the wound has healed perfectly. There is no depression at all, and one finds only a smooth linear scar. The patient's hearing is well preserved. The wound in the leg healed by primary union and did not cause the patient the least inconvenience.

I have also used this method in two other cases which I will briefly detail:

Case II.—A young girl, L. F., aged 14 years, was operated upon one year ago for a double mastoid, and discharged as cured. On July 15 of this year she was readmitted into the hospital, as her left ear again discharged and her mastoid also became involved. I performed a secondary operation on the 17th. Ten days later, July 27, I did a tibial bone transplantation and sutured the wound with the exception of a small gutta-percha drain just as in the previous case. In removing the bone from the leg I injured the periosteum, owing to a slipping of the saw. Nevertheless I used this transplant. The wound was perfectly clean and covered with granulations, as far as I could judge, yet within a few days the edges came apart but the bone remained in place. I applied wet dressings and removed the drain, at the same time touching the edges with a 10 per cent. solution of silver. Subsequent dressings consisted merely of applying sterile gauze and an antiseptic powder.

On August 26, 1912, the patient was discharged with the wound nearly united. It failed to close completely, however, as a portion of the transplanted bone acted as a foreign body, which, being removed, allowed the wound to heal rapidly. It is now ten weeks since closure of the wound, but owing to its failure to close by primary union, the cosmetic result is not as good as it might have been.

Case III.—A young lady, F. K., 20 years old, was admitted into the otological service of Mount Sinai Hospital on September 1, 1912, with an acute suppurative, left-sided otitis media of four days' duration. The drum had ruptured spontaneously and there was a profuse purulent discharge. The mastoid process was exceedingly painful. I performed the ordinary Schwartze-Stacke operation on the following day, September 2, 1912. Dressings were changed every other day. On September 19, having a clean granulating wound, I did a tibial bone transplantation. Four days later the sutures and gutta-percha drain were removed. Unfortunately I also injured the periosteum in removing the bone from the tibia, as in the previous case. The edges of the wound separated somewhat, but closed by granulation, the transplanted bone remaining *in situ*. The patient was discharged from the hospital on October 1. For a few weeks thereafter the superficial dressings were changed every other day and the wound edges touched with a 10 per cent. solution of silver nitrate. There is a slight depression behind the ear, but the transplanted bone has been retained. It is now a period of six weeks since closure of the wound, and there has been no reaction. I believe that had there been no injury to the periosteum, union would have been better and more rapid. The hearing is well preserved.

*Technique of Bone Transplantation.*—The piece of bone which I use for the transplant is taken from the crest of the patient's tibia. As a matter of convenience I select the leg corresponding to the side of the mastoid wound. The operation is performed under general anesthesia, although it is perfectly feasible under a local anesthetic.

Having removed the packing from the mastoid cavity, I freshen the edges so as to obtain a better union, but do not touch the granulating surface of the wound itself. In the meantime an assistant prepares the leg over the tibial region. I then make an incision 6 or 7 inches in length down to the periosteum, but exercise care not to injure it.

With a bent probe I now measure the distance from the upper to the lower angle of the mastoid wound and mark off the corresponding length on the exposed priosteum. I then outline with a sharp scalpel the piece of bone I wish to remove, cutting through the periosteum to the bone itself, but being careful not to cause any injury. I usually outline a quadrangular bone flap, from half an inch to one inch in width, the length varying according to the mastoid wound.

Having done this, I bore a small hole with a bone drill through the crest of the tibia, about half an inch below the surface. Through this I pass a small Gigli saw as shown in the diagram, Fig. 1.

This is fastened into the handle of a scroll saw and one then removes a bone flap as shown in Fig. 2, so that the raw edges are somewhat beveled. I find it better to use a saw than a chisel for this purpose, as there is less possibility of injuring the

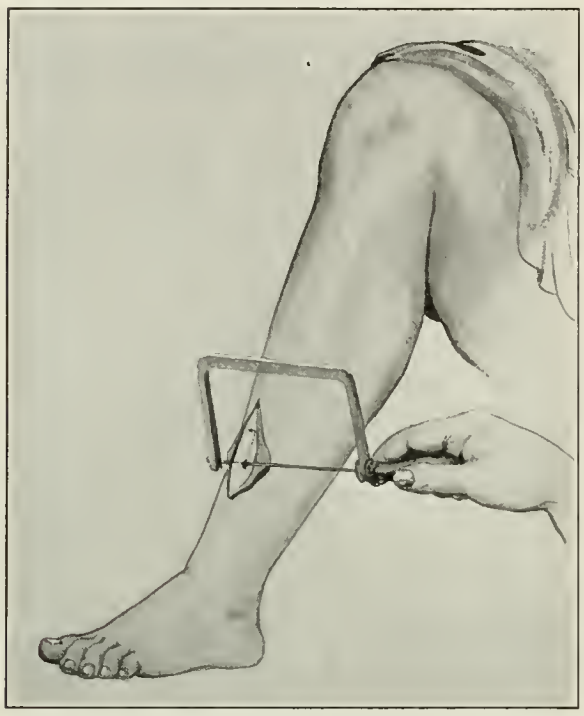

Fig. 1.—Exposed crest of tibia showing Gigli saw introduced through drill hole, and bone flap with periosteum outlined by dotted lines.

periosteum, and if one follows this little precaution of first drilling a small hole the saw cannot slip.

The bone with its periosteum now being detached, it is carefully immersed with a pair of forceps into warm saline solution. It is thereupon placed into the mastoid wound as quickly as possible in such a manner that its raw surfaces come in contact with the clean granulating surfaces of the mastoid bone itself. The skin is then carefully sutured with the exception of a small orifice in the lower angle, in which I place a small piece of gutta-percha drain for a few days.

If at the end of three or four days I find that there is merely a slight mucous or mucohemorrhagic discharge, I remove the drain and allow the opening to close entirely.

The transplanted bone acts as a bridge, as shown in Fig. 3, and upon this rests the skin of the mastoid region. From the transplanted living periosteum new osteogenetic cells penetrate into the transplanted bone and gradually replace it by new formed bone, whilst union between the transplanted periosteum and the periosteum of the adjacent bony tissue also takes place.

The air space below the transplant fills up with a blood clot, which becomes organized and eventually replaced by new bone from the transplant, so that after a time the cavity becomes obliterated.

It is important to remember that even in cases in which the bone transplant is exfoliated, portions or the entire transplanted periosteum remains. It eventually produces a new bone formation, which fills the defect created by the operation.

In performing bone transplantation one must observe the following precautions.

(1) The postoperative mastoid wound must be free from purulent secretion and covered with healthy granulations.

(2) The wound must not be curetted or bathed with antiseptic solutions.

(3) Transplantation must be performed as a secondary operation, and may be undertaken a week, ten days, or even longer after the primary operation, depending entirely on the condition of the mastoid cavity.

(4) The bone flap must be taken from the patient's own tibia; in other words, an autogenous transplantation.

(5) Bone alone is insufficient; one must always take the bone with its living periosteum attached. This has been conclusively demonstrated by the experiments of Ollier[10] as early as 1858, and confirmed later by Radzimowsky,[11] Marchand,[12] Bonome,[13] and others, and more recently by Auxhausen.[14] The consensus of opinions of most investigators proves that in order to make a bone transplant viable it is imperative to preserve the healthy living periosteum.

(6) The periosteum must not be injured; for, if it is, the ultimate result will be doubtful. The chances of success are much greater with an uninjured periosteum.

(7) In making the bone flap, one must handle it as little as possible, so as to avoid injury and infection.

(8) Inasmuch as a good blood supply is absolutely essential to the successful issue of all kinds of transplantation it is advisable to make use of this method only in such cases in which a good vascular bed for the transplant is present. This would exclude those cases in which there is a hard, ebonized sclerotic mastoid bone.

Transplantation of the bone in mastoid surgery is a procedure which I do not advocate as a routine measure. I am of the opinion, however, that it is of value in cases in which there is a clean granulating wound, for if we succeed we not only obtain a better cosmetic result and greatly shorten the time of healing, but we also overcome the packing and repacking of the wound as is customary in the usual open method.

I may state that the procedure has one drawback,

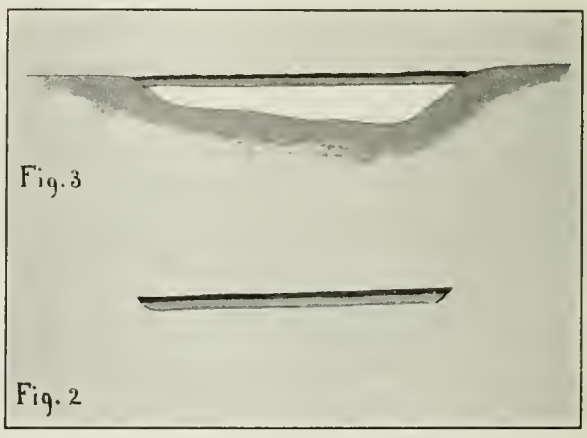

Fig. 2.—Lateral view of bone transplant, showing layer of periosteum and the raw beveled edges.

Fig. 3.—Mastoid cavity showing bone transplant with its periosteum in position, and air space below.

if one may call it so, and that is that the patient is subjected to a second general anesthesia. However, I believe most patients will readily submit to this, if they can be convinced of the time and annoyance saved in the after treatment. There is no doubt

that the method is perfectly feasible under local anesthesia, as already stated.

Exposure of the sinus and dura, I do not consider a contraindication to a bone transplantation, for if these parts are covered with healthy granulations there is no reason why the result should not be satisfactory. I was asked if there was no danger of a retention of pus beneath the transplanted flap with a secondary infection of the surrounding structures, as the sinus, etc. I do not believe that this is likely to occur, for, if there is a suppurative process going on beneath the transplant, union will not take place, and the bone will be exfoliated within a very short time. Under such circumstances, transplantation will fail, and one is compelled merely to resort again to the usual open method of treating the wound. In other words very little has been risked and we have given the patient a chance for a more rapid and painless recovery.

In conclusion I wish to state that a few cases are indeed insufficient to prove the value of any surgical procedure. However, I feel that the encouraging results obtained by these first attempts at a solid bone graft in a mastoid wound, and as far as I know the first attempts of this kind, demonstrate the feasibility of this method and trust that future cases will prove it of value in the postoperative treatment of mastoid wounds.

## JUNG'S MODIFICATION OF THE FREUDIAN THEORY OF THE NEUROSES.*

By S. P. GOODHART, M.D.

NEW YORK.

The radical conceptions of Freud, with especial reference to the theory of the origin and cure of hysteria and the neuroses, although for some years lying dormant, have been, as we all know, within the recent past suddenly revived and have gained a strong hold upon scientific thought both here and abroad. Bitter as was the opposition to the Freudian theories among the majority of psychiatrists, yet staunch were many of his adherents.

*Paper read before the Neurological Section of the New York Academy of Medicine, November, 1912.

Perhaps no observer has so judiciously and in such an unbiased manner studied the Freudian doctrines as has the eminent psychologist Jung of Zürich. Originally an investigator of these theories and a supporter of them, he has gradually found himself going further away from them in their originality. The virulent criticisms assailing them have likewise been applied to Jung, although he has often expressed himself as one in search of truth and studying the subject with an unprejudiced mind.

Those who heard the most recent expressions upon the subject by Jung himself must have been impressed with the brief but comprehensive discussion of psychoanalysis which he delivered in October before the Neurological Section of the Academy of Medicine. However, the discussion which his remarks evoked indicated that the radical departures from the Freudian doctrines were not entirely grasped; in a conversation with the writer a day or two later it transpired that Jung himself was of the same opinion. With his approval I have undertaken a brief, critical review of his argument.*

As is well known, the original idea that hysteria and related neuroses took origin in trauma or mental shock of a sexual nature in early child life was given up fifteen years ago; for, as Jung says, it soon became obvious that sexual trauma itself could not be the real cause of a neurosis, since almost every human being has had a sexual shock in early youth, though of course we know that this serious consequence, a neurosis in later life, is relatively infrequent. Freud himself, the original expounder of this idea, soon learned that sometimes patients in whom an early traumatic event of a sexual nature seemed to be the basis of their psychoneurosis really invented the story, it being with them a phantasy or, in other words, a representative experience constructed entirely as a result of their mental imagery.

Through further investigation it became obvious that even a trauma which had really occurred could not always have produced such a violent effect as one sometimes determines through psychoanalysis; this apparent effect is really not so much the trauma itself, even if that trauma has occurred, but rather a morbid phantasy. Freud showed that sexual phantasy reaches back to early infantile age when it is connected with, or preceded by, bad habits and so-called infantile sexual perversities. In this conception of the etiology Freud traced back the neurosis to some sexual activity in early infancy, and this conception led him up to his more recent view that a neurotic is, so to speak, *transfixed* to a certain period of his early infancy; he even makes the attempt to classify or differentiate the particular neurosis according to the time or stage of infantile development in which the so-called "fixation" occurred.

From this standpoint the neurotic appears to be entirely dependent upon his infantile past, and all the morbid psychic manifestations in later life, the moral and intellectual conflicts develop through the powerful influence of the past. The Freud therapy and its leading thought is in full accordance with this theory, conceived by its author as an unraveling of subconscious attachment of the sexual "libido" to infantile phantasies and habits. Restoration to health demands that the "libido" become detached from the subconscious phantasies or infantile fixation.

This sums up briefly the essence of Freud's

*The author is indebted to Prof. Carl Jung for his kindness in reviewing this paper.

theory. Jung pertinently remarks that this conception warrants the important inquiry as to the reason of the fixation of the libido to the old infantile phantasies and habits. Nearly all of us have had infantile phantasies and habits corresponding to those of the neurotic; still we do not all become fixed with them, and do not necessarily become neurotic later on. The etiological element of the neurosis, therefore, does not consist of the mere existence of infantile phantasies, but must then be contained in the so-called fixation. All the manifold statements of the existence of infantile phantasies in cases of neurosis are worthless as having etiological significance, for the same phantasies are often found in normal individuals. To this, those of us who have had a larger experience give absolute concurrence. Hence it is only the fixation itself which seems to be characteristic.

Jung is careful to do full justice to the sincerity of Freud, and thinks that his investigations of psychoanalysis led him very reasonably to this hypothesis. Psychoanalysis, as we know, unveils the subconscious existence of manifold sexual phantasies which may have their final root in the infantile past and which often revolve around what the Germans have called the *kern*, or nucleus complex. This so-called complex, or subconscious system, has been spoken of in the male as the Œdipus complex and in the female as the Electra complex. These terms refer to the sexually emotional relationship between the son and the mother, or the daughter and the father.* Freud lays great stress upon the importance of this as a common point of fixation. As Jung says, the mere existence of this so-called conflict cannot be characteristic of the neurotic, since in some form there exists in all of us this complex in the subconscious. It is characteristic of each neurosis that the patient appears to be strongly attached to his complex.

Much has been said of this Œdipus and Electra complex; probably its importance has been unreasonably emphasized. In neurotic children it seems that phantasies are prone to assume a sexual character. A morbid affection, Œdipus complex, may not infrequently be bound up in such a neuropathic constitution. The Œdipus or Electra complex, according to both Jung and Freud, is always present. Its presence can be postulated. The only question is whether or not it becomes reinforced in emotional upheaval so that when neurosis develops it stands out and becomes a prominent factor. In neurotics the Œdipus or Electra complex is of great importance. The question arises, is the intensity of the complex derived from fixation or from regression? Here there is an apparent difference of opinion between Freud and Jung.

We must admit that the hypothesis of fixation has more to commend it, since it is known that certain periods of human existence, especially the early years, the pubescent and adolescent, leave a determining trace throughout life. The pertinent question is whether or no this explanation is sufficient. It is true that in some cases the neurosis seems to have been present since the time of infancy, the nucleus complex having remained permanent and powerful throughout the entire life of the individual. If, however, we study the many cases that never show traces of neurosis and apparently become ill at a late period of life, the applicability of this principle becomes doubtful. If there is really a fixation, are we not allowed to base a new hypothesis upon this principle that sometimes, and at certain periods of life, the fixation becomes loosened and inefficacious, while at other times it suddenly becomes strengthened?

As a matter of fact it is a common observation that the outbreak of the disease rarely occurs at an indifferent time, but usually at a critical psychological moment and when a new psychological adjustment or adaptation is demanded. If fixation were the invariable basis of the neurosis we might expect a constant influence of it; that is, a constant neurosis throughout life. This is surely not the case. Jung refutes the idea of fixation, as expounded by Freud, in so far as the former does not believe that it is a question of an abnormal fixation to a certain complex. According to Jung, there is a certain conservatism preserving ancient infantile ways of adaptation or infantile attitude. This is in itself a normal phenomenon and cannot be called "an abnormal fixation." Therefore, even in neurosis it is not that there is abnormal fixation. The neurotic, it must be remembered, has some very individual tasks in life—tasks, efforts, impulses not readily understood. The neurotic is obliged to relinquish, to give up much more of his infantile attitude than a normal being; the latter can remain unconscious of the many callings from within; need not make the constant effort at adaptation; can remain, as one might say, "unconscious of himself" throughout life. The normal being simply follows established lines, the usual avenues of life. He is not a "peculiar" being, has no particular and very individual life tasks. Jung gives the term "regression" a conceptual application more complete than does Freud and in this wider conception applies it as herein described.

Jung believes that all psychological phenomena may be considered as manifestations of energy in the same manner that all physical phenomena are so considered. This energy, variously conceived as desire, or any form of inherent force, he speaks of as the "libido." In a broad sense, he regards it as the vital energy. Its first manifestation he sees in the suckling as the instinct of *nutrition*. It will be recalled that Freud, on the other hand, considered this as *sexual* in character. Jung's conception of the transformation of the libido, its development through the phases of nutrition, sexuality, and the higher functions is splendidly elucidated in his work "Wandlungen und Symbole der Libido."

In the presexual stage of development the *libido* is still in part a *nutritional* function. In the *period of childhood* the libido first appears entirely in the form of an *instinct for the partaking of food* which provides for the growth of the body. As the body develops, new domains are opened up successively for the application of the libido. The last domain for its application, predominant in its functional importance, is the sexuality which originally appears extraordinarily dependent upon the nutritional function. (The influence of nutritional factors on propagation of the lower animals and plants.) It is in the domain of sexuality that the libido acquires a shaping of tremendous significance so as to justify the employment of the term "libido."

*In the Iliad it is related that Œdipus, not knowing his mother, when he met her, misjudged the nature of his filial love and married her.

The normal love of a daughter for her father was perverted in Electra by her desire for revenge for his murder, so that its strength incited her to connive at the assassination of her own mother by her brother.

These are the most striking examples in history, or tradition, of this form of complex.

The libido here manifests itself as the instinct of propagation; originally in the form of an undifferentiated vital energy of growth.

Jung, when he refers to "libido," associates therewith the genetic concept which enriches the recent sexuality by an arbitrary amount of desexualized, primary libido—"urlibido." The transference of Freud's libido theory to psychotic conditions becomes possible only through this genetic concept of the libido, which in all directions extends beyond the recent sexuality.

The libido of the young at first manifests itself exclusively in the zone of the nutritional function; in the act of suckling, the food is ingested through rhythmic movements with all organs of pleasure and satisfaction. As the individual grows and his organs develop, the libido seeks new avenues for its needs, its manifestation, and its satisfaction. The primary model of the rhythmic function, which produces pleasure and satisfaction, must now be transferred to the zone of other functions with the ultimate goal in the sexuality. A considerable part of the hunger libido must be transformed into the sexual libido. This transition does not take place suddenly at the time of puberty, but it occurs very gradually during the course of the greater part of childhood. The libido must free itself with difficulty and very slowly from the peculiarity of the nutritional function in order to enter into the characteristics of the sexual function. In the course of its ingestion the libido carries considerable material from the nutritional function into the sexual zone, thus readily accounting for the numerous intimate connections between the nutritional and the sexual function. When, after the conquest of the sexual zone, an obstacle of any kind arises against the new form of application of the libido, a regression takes place to the just passed earlier stages.

Normally liberated, the libido finds expression in desire, ambition, endeavor, etc., and is, in maturing adult life, devoted to an adaptation to the external world. Whenever the application of the libido, in the process of adaptation, meets with an obstacle, in the normal individual there is an accumulation, a damming, or storing up of this energy, manifesting itself in an increase of effort to overcome the obstacle. If the difficulty assumes unsurmountable proportions and the individual renounces the idea of overcoming it, the libido or energy becomes, figuratively speaking, anchored, and a *regression* results. This is to say, the libido gives up the task and, in the neurotic, assumes a former and more primitive adaptation. Jung understands this process of regression as a tendency to assume former juvenile life habits that have been stored up within the subconscious.

In his work, "Metamorphosis and Symbolism of the Libido," Jung develops the psychology of regression. Thought processes are conducted in two ways: (1) As directed thought, in which there is conduction in language only. This form produces new material, adapts, initiates reality, and attempts to deal actively with it; the attending mental processes are fatiguing; they demand constant energy liberation. (2) Associative thought, as in dreaming, thinking in pictures, or in the waking state as in revery, day dreams, etc.

Dreaming in pure imagery is attended by practically no mental effort; it is the use of spontaneously appearing reminiscences. Reality is disregarded, subjective desires are liberated. Here there is no productiveness in regard to adaptability. We can readily see here how the activity of the subconscious demonstrates itself. Waking or directed thought is progressive. Dreaming or associated thought is regressive. Here is indicated how the phantasies of child life, stored up in the subconscious, find their re-enaction in the regressive period following a psychic upheaval. Progressive thought ceases and associative thought and imagery —regressive psychic process—takes its place. By psychoanalysis the same mental state may be induced as in dreams in which regressive thought-excitation from the subconscious may be stimulated and the sometimes hidden desires of a personality revealed.

Thus we see the neurotic in time of psychic conflict and consequent regression returning to a primitive method of thought—associative thinking in imagery—as does the child and as did primitive peoples. Phantasies, too, thus arise; to the child the moon is a man, a shepherd of the stars; the clouds in the sky are sheep; a dog the husband of a cat, etc., etc.

Psychologically speaking, phantasy I understand to be a form of mental representation of psychic images, often of subconscious origin, quite distinct and severed from their usual relationship in actual experience. Someone has well defined a phantasy as a form of imaginative ornamentation—not to be taken with indubitable credence, but as allowable of an imaginative mind's vivid coloring and rich embroidery in the coarse texture and dull neutral tints of truth. This well illustrates the form that phantasy may take; often based upon an experience, it at times assumes a grotesque form, or again is perverted into some elaborated idea. The phantasy rarely, or never, is the bare experience and is often a purely fanciful construction. The form and character of these phantasies reveal the nature of the pathological psychic content.

The juvenile life of the neurotic is, as we all know, full of emotional upheavals and unstable psychic processes, and I take it that Jung assumes that the process of regression brings to the surface these morbid entities. The disturbance may give rise to defects of nutrition, manifested as disturbances of metabolism and various hysterical outbreaks—psychic regressive manifestations. Here we may even have a revival of the so-called Œdipus or Electra complex. It is observed that the events of juvenile life suddenly assume unreasonable importance or are regressively animated, so to speak.

Finally, taking issue with Freud, Jung says that if we could take off this immediate impediment that is present in the path of life, the whole system of infantile phantasy would at once break down and become inactive. We cannot do this as a rule, and hence the obstacle must be overcome.

To return to the subject of phantasy:

The whole coterie of infantile phantasy, the real and the fanciful experiences of child life, do not give any etiological explanation of the neurosis; nor does fixation; the real issue lies in the inflating, so to speak, through the regressive libido, which has not found its natural outlet. In this we observe a most important therapeutic suggestion; namely, the proper directing or adaptation of the patient's libido in harmony with his environment. A sensitive and somewhat disharmonious character, as the neurotic often is, will meet particular difficulties and more unusual tasks in life than the more normal individual who, as a rule, has but to follow the well-established line of the ordinary. The sexualisms of

the neurotic phantasy are only secondary, being a consequence and not a cause of regression. The real cause of a neurosis is an innate resistance against new adaptations; not, as Freud says, infantile perversions.

Through psychoanalysis one seeks only to establish the connection between the conscious and the desire, the libido, in the subconsious, through restoring the energy or wish or desire to the field of consciousness; in this way the formerly split-off libido becomes again applicable to the new tasks of life. The suppressed desires of the individual should be brought forth and mirrored, so to speak, so that the subject may learn to make a voluntary selection and see for himself just what his attitude must necessarily be in the situation in which circumstances have thrust him. With the gentle, the patient, the persuasive operator the narrow, obstructed path will widen to the comprehensive view of the subject.

I am inclined to believe, however, that there are experiences that lie within the subconscious and entirely forgotten experiences of juvenile life that must of necessity in many instances be brought to consciousness, since I am sure that they have a directly operative influence upon the waking self.

From this standpoint psychoanalysis does not appear to be a mere reduction of the individual to his primitive desires, but rather an educational process, one tending to the development of strength, character, and directed will in the patient. Jung disapproves of the attempt in psychoanalysis invariably to force out the remote past. He doubtless believes that these juvenile experiences may, figuratively speaking, undergo sclerosis, the important elements being really disintegrated and having no influence upon the later mentality of the individual. He believes, however, that the juvenile experiences have of course a certain influence upon the later formation of a personality, but not the exaggerated influence which they apparently have in neurosis; here they become exaggerated, inflated, through regression. In psychoanalysis Jung adds the attempt to discover a way to the unsurmountable task and to find the manner of its accomplishment. The technique of psychoanalysis requires an understanding of the purposes of the method, and, if carried out according to the latest ideas of Jung, need never offend the sensibilities of the most reserved.

Psychoanalysis, then, as we now view it, has not a destructive, purely analytical purpose; it is rather constructive in an effort to synthetize the natural forces of the individual, directing him and enabling him to find himself; to lead him into an avenue which will afford a natural outlet for his creative ability, or energy, or libido. It is indeed an educational endeavor, making for the upbuilding of all which tends to develop the best within the individual. It is a scientific opposing force which rationally meets the demand that has given rise to the deteriorating influence of the various cults, isms, and all the demoralizing institutions of mental malpractice.

34 West Eighty-seventh Street.

**Physician and Pharmacist—Sale of Liquor.**—The Washington statute, prohibiting the sale of liquor generally, with or without a license, within 2,000 feet of any normal school, is held to apply to a physician who was a pharmacist, prescribing whisky for a patient as a physician, and filling the prescription at his pharmacy within the prohibited district.—State v. Pomeroy, Washington Supreme Court, 123 Pac. 514.

## POST-OPERATIVE GASTROENTERIC PARESIS.*

By James Taft Pilcher, M.D.,

Brooklyn, N. Y.

The occurrence of acute dilatation of the stomach and the usual concomitant paresis of the gut after operation has always been considered a most serious complication, and the percentage of deaths that has been attributed to it would probably be much greater if all the cases had been correctly diagnosed. That it is not so rare a condition as has been heretofore supposed is evidenced by the fact that within the hospital experience of the writer over sixty cases have been observed.

In a recent statistical review comprising some 225 cases (Nicolls) the mortality was stated as having been between 65 and 70 per cent. In this present series of sixty personal cases the mortality has been below 5 per cent. due, we feel, to the earlier recognition and immediate institution of proper treatment. In the last twenty patients there have been no fatalities.

*History.*—The most imperative feature of this class of cases, the acute dilatation of the stomach, was recognized as far back as 1842 by Rokitansky, who considered the condition the result of a mechanical obstruction, owing to the fact that he observed a case in which the duodenum was compressed by the root of the mesentery and its contained vessels. Brinton, in 1859, published the results of a careful study, and concluded that the acute dilatation was of paralytic, rather than of mechanical origin. But it was not until 1873 that Hilton Fagge, in the eighteenth volume of Guy's Hospital Reports, gave the first clear and concise description of the condition which has not been improved upon as regards the description of the symptomatology and diagnosis, even by many writers on this subject at the present day.

Acute dilatation of the stomach and the accompanying paralysis of the intestine has been described under many titles which represent the pathologic-anatomic pictures presented in the cases observed, usually post-mortem, such as pseudoileus, arteriomesenteric ileus, gastromesenteric ileus, mesenteric incarceration of the bowel, post operative arteriomesenteric intestinal obstruction, acute paralysis of the stomach, post-narcotic gastric paralysis, acute duodenojejunal intestinal obstruction, combined ileus, duodenal ileus, duodenal compression, and post-operative acute dilatation of the stomach.

This chaotic condition of nomenclature is another instance of the pernicious results which may follow the drawing of conclusions from post-mortem observations alone since these may give one impressions absolutely erroneous, as has been so conclusively demonstrated lately to have been the case in the compilation of statistics as to the relative occurrence of gastric and duodenal ulcer, pancreatitis and the correlation of ulcer and cancer of the stomach. One cannot draw proper conclusions as to the preexisting physiologic and anatomic relations of an organ which has been deprived of its innervation through death, the study must be based on the living pathology of the organ considered.

*Phenomena of Occurrence.*—Acute dilatation of

*Read before the Kings County Medical Society, Brooklyn, N. Y., March 19, 1912, and before the Society of Alumni of Bellevue Hospital, February 7, 1912.

the stomach *per se* has occurred many times without a preceding operation, cases having been recorded during convalescence from typhoid fever and pneumonia, also in the course of severe debilitating diseases, in the acute infectious diseases and as a result of brain and spinal injuries. Scattered instances are found of acute atony consequent to overindulgence in food or liquids, and in many instances merely eating a very small quantity of certain substances, usually of an innocent nature, has caused dilatation of the stomach through the formation of gas, from which the patients have suffered the most acute distress, and in some unconsciousness has supervened. The most surprising element in this class of cases is the continued production of such great quantities of gas. Many of them suffer a repetition of the dilatation on the slightest error in their diet, the attacks usually following over exertion or conditions of general fatigue. Four typical instances have been observed by the writer of this class of non-operated cases. One of particular interest seen in consultation with Drs. Williams, Bird, and P. M. Pilcher, occurred in a middle aged man, who had no previous indication of stomach trouble and seemed to result directly from having eaten moderately of some smoked herring and caviar. About one hour later, without giving any premonitory signs, he suddenly fell from his chair and almost immediately became unconscious, remaining, however, in a state of normal tonic spasm. Examination disclosed an enormously distended abdomen. On introduction of a tube the gas escaped in such quantities and with such force that it was to be heard distinctly twenty feet away. In fifteen minutes the stomach was again noted to be distended and a similar phenomenon was evoked on the second passage of the tube. The formation of gas was checked by thorough lavage, and in a short time consciousness was regained, the patient feeling perfectly well the next morning. What caused such an extraordinary production of gas, I am unable to explain, but surmise that the attack originated as a result of some toxin, and the syncope was consequent to displacement of the heart.

The cases considered as the basis of this communication followed direct trauma of the upper abdomen in the majority of instances, and were particularly sequelæ of gall-bladder operations. The minority comprised cases of appendix, colon, uterine, and kidney manipulations.

It may occur at any age; Nicolls reports an instance at nine months, and Lucas one in a child eleven months old. From these the extreme is reported by Smith, as occurring in a patient of seventy-four. The average, however, is between twenty-five and thirty-five, probably because more people are operated on at those ages than at any other. There seems to be no predilection of sex.

*Etiology.*—In order to be able to intelligently treat any condition one should have a thorough understanding of its etiology, and this is particularly pertinent as regards the question of gastroenteric paresis. The two questions for consideration primarily are: Is the condition mechanical or paralytic? Both premises have for many years had adherents, those of a mechanical conception fathered by Rokitansky in 1842, and those maintaining a primary paralytic factor, following the precepts laid down by Brinton in 1859.

There is no question that both factors are present when the condition has developed—but which is primary? Does the dilatation cause the kinking in the duodenum, or does the kink in the duodenum cause the dilatation? As Smith has so definitely demonstrated, "the evidence favoring compression of the duodenum by the root of the mesentery as the primary factor in producing dilatation of the stomach is equally conclusive that the compression is secondary. The evidence is post-mortem," and any observations made from such examination show the end results, not the inception. The compression does not account for the inability of the stomach to empty itself by vomiting nor will it even account for the stomach being dilated. The writer has seen several hundred cases of pyloric and duodenal obstruction from cancer and ulcer and in only a very few cases was there any considerable atony of the stomach, and in none acute dilatation, and further, in no instance was the vomiting reflex absent.

Nicolls found, in analyzing a large series of autopsied cases, only one-third of them showed evidence of duodenal compression. Possibly more illustrative is the fact that acute dilatation has occurred in several instances after a gastroenterostomy, which was found patent at autopsy. All of these clinically observed phenomena have been satisfactorily and conclusively substantiated by experimental studies and would indicate that *the compression of the duodenum is secondary.*

How are we to explain its occurrence, for it does occur, as shown by the regurgitation of bile, indicating that the obstruction is distal to the papilla of Vater, and high up in the intestine, evidenced by the lack of fecaloid odor, and further, by its absolute demonstration at autopsy.

The key to the whole situation may be found in the title of this paper—"Gastroenteric Paresis," for the acute dilatation of the stomach is only one factor in the picture, though the most important from a systematic view; the paralysis, as demonstrated by Smith, is not local in its effects. "There is present a general alimentary paralysis and the primary obstructing factor is to be found in the paralyzed bowel," as will be readily appreciated by those accustomed to doing intraabdominal and intestinal surgery, any portion of the gut suffering from a lack of peristalsis offers a relative obstruction and in these cases the entire upper intestine has lost its property of propulsion as well as the stomach.

With these facts in mind consider what occurs at the only absolutely fixed portion of the small intestine, namely, the transverse duodenum, where it is crossed by the root of the mesentery. Nicolls and Smith pictured it clearly in stating that "there is what may be termed a physiological tendency to obstruction or constriction,—a potentiality that may become an actuality from an apparently trifling cause." This factor is present in the paresis of the intestine, the potential obstruction quickly becomes an actual one, the secretions from the stomach and duodenum continue to be poured out and the vomiting reflex is absent. Thus a vicious circle is formed, each factor accentuating the other.

Considering these facts, it seems reasonable to conclude that the original factor in the production of gastroenteric paresis is not to be explained on a purely mechanical basis. This then leads to but one inference that the condition must be one

of nerve exhaustion produced either through direct trauma or through reflex impulses.

In substantiation of this inference we have confirmatory experimental evidence. Cannon and Murphy have proved that excitation of the splanchnic nerves markedly inhibits both gastric and intestinal peristalsis, while Braun and Seidel have demonstrated that if the vomiting reflex is destroyed by cutting the vagi, acute dilatation invariably occurs. Further, Smith has shown that this condition ensues whether the pylorus or duodenum be stenosed or not, indicating therefore that interference with the action of the vagi inhibits peristalsis as well as the vomiting reflex. This interference with the normal nerve tone of intraabdominal structures is probably caused in the majority of cases reflexly, as it very infrequently follows operations on the stomach itself, but rather manipulation of adjacent organs. The nearer their situation to the semilunar ganglion the more frequent the occurrence of post operative paresis, as is indicated by considering that the majority of cases have occurred after operations on the biliary passages, duodenum and pancreas. To this list the writer would add operative manipulation of the kidney, which has very frequently been noticed to be followed by epigastric distress to a greater or less degree. Kelling, Payer, Smith and others attribute the paralysis to the action of the narcotic, particular stress being laid on ether. But their conclusions are vitiated by the fact that acute gastroenteric paresis has occurred after operation done under local anesthesia, as in a typical case reported by Lyle, in which an inguinal hernia was done under the combined infiltration and intraneural method. Recurrence occurring shortly necessitated a secondary operation which was done under ether anesthesia, which resulted in an uncomplicated convalescence. The writer has seen the most obstinate paresis occur after the use of nitrous oxide for the very short period of time necessary for an amputation at the knee.

Kuru and Morris suggest that the chromaffin secretions are disturbed through shock or the production of toxins, and the suprarenal gland being the chief elaborator of such hormones, suggests the thought that possibly the temporary exhaustion of this gland may be responsible for the resulting paralysis as its secretion seems to have some property for regulating the action of the stomach.

Witherspoon concludes from an experience in two cases that intoxication from the overactivity of the colon bacillus in the bowel may possibly prove of etiologic import, but neglects to appreciate that in many instances where we have known foci of extensive colon infection there is no accompanying paresis of the gut. Hendon also attributes the phenomena to absorption of peculiar and highly specialized toxins of unknown nature.

The writer feels, however, that the simpler explanation, namely, paralysis due to reflex inhibition is much more probably correct, as experiments on dogs in which the adrenals have been extirpated have not shown that the stomach or intestines have become paralytic and further the results of treatment based on other premises than that of inhibited adrenal secretion have proved most satisfactory.

*Symptoms and Signs.*—The symptoms are few, characteristic and easily recognized, but are frequently overlooked in the general activity of many hospitals because at first they are considered merely a prolongation of the usual sequelæ of etherization. The cardinal factors in this condition are vomiting, distention and collapse. Of the less important symptoms, pain, thirst, and obstipation complete the picture.

There is a prodromal symptomatology, which is very suggestive, consisting principally in restlessness, depression, excessive thirst, increasing rapidity and feebleness of pulse, and scanty urine, which collectively are quite as reliable guides, if appreciated, as is the regurgitation and distention itself.

Vomiting is a misnomer, as that is not what occurs in the general acceptance of the term, in acute dilatation of the stomach. Regurgitation is, however, much more descriptive. The stomach is emptying itself from overflow, the cardia acting as the safety valve. These tremendously dilated stomachs do not burst, but the slightest movement of the body causes its contents to *well up* into the mouth. In the terminal state it may be profuse, but it will usually be noted at first to consist merely of mouthfuls at varying intervals of bitter, acrid, greenish, frequently coffee-ground material which appears without any appreciable effort on the part of the patient.

This phenomena may be a continuation of the post anesthetic nausea and vomiting. More frequently, however, there is an interval of several days before dilatation occurs, or in many instances, there may have been no immediate post operative vomiting, and nausea and regurgitation were first noted to occur between the twenty-fourth and forty-eighth hour, appearing seemingly without any evident cause. Such a report should at once direct the physician's attention to the abdomen, which will be found greatly distended after the removal of the ever-present, well-reinforced, secretive abdominal binder.

Distention.—The writer has not observed any of the socalled typical pictures of acute dilatation of the stomach where the outlines of the organ were perfectly traceable through the abdominal wall, and the remainder of the abdomen flat. The distention has always been quite general, possibly more marked in the left hypochondrium and epigastric quadrant, and he fully agrees with Smith that the very fact that a large percentage of deaths and autopsies have been reported is good proof that the condition was not recognized early, if at all, and the flat abdomen observed in these cases is the result only of the enemas employed, while the patient died from the unrecognized dilatation of the stomach.

Collapse.—There rapidly develops in this condition an almost pathognomonic languor and apathy on to which there is engrafted, usually within twenty-four hours, very evident symptoms of collapse, recognized by the small, rapid and almost running pulse and the rapid shallow respirations.

Pain.—The pain complained of is not as a rule a marked feature. It is more frequently characterized as a distressed feeling or one of fullness or pressure, usually upward, impeding respiration. There is one point of pain, however, which has been noticed in several cases and corresponds to the position of the root of the mesentery, where it crosses the duodenum.

Thirst.—In many instances thirst has been the chief complaint, and it is for some time impossible to relieve it as no fluids introduced are absorbed.

Obstipation is absolute.

The temperature is seldom affected or at most is

at great variance with the obvious intra-abdominal condition were it anything but gastroenteric paresis.

*Differential Diagnosis.*—There are but three conditions which could possibly confuse the observer in making a differential diagnosis. *Acute pancreatitis* is the most difficult of these, and particularly when considering instances of acute abdominal paralysis in non-operative cases. The antecedent history may afford no clue, and even the local condition may appear on superficial examination to be the same; as in acute pancreatitis, the first few feet of the small intestine are almost invariably paralytic and distended, but on introduction of a tube, the stomach will not be found to be dilated and the vomiting reflex is present. The pain is very much more intense in pancreatitis, but the onset and general picture of the collapse may be almost identical.

Acute intestinal obstruction is relatively simple to differentiate, as the stomach is never dilated and the vomiting usually occurs early and is of a projectile nature and frequently fecaloid in character.

Acute perforative peritonitis offers to the clinician an increasing leucocytosis and rising temperature, and locally, general rigidity and uniform tenderness, and the stomach is not found dilated at the inception of distress.

*Prognosis.*—The prognosis in untreated cases is bad, probably resulting in a mortality of 70 per cent. In cases recognized at their inception and properly treated the mortality is reduced to practically *nil*.

*Treatment.*—Treatment may be considered under the captions Prophylactic and Active.

*Prophylactic.*—Thorough evacuation of the intestines before operation. The intramuscular or intravenous injection of 20 to 40 c.c. of hormonal before operation in suitable cases. A minimum manipulation of the intra-abdominal structures, particularly those in the upper abdomen. The introduction of two quarts of saline solution at 110° F. into the rectum in a lithotomy position at the conclusion of all intra-abdominal operations. A minimum use of ether or chloroform, and administration by the open method, and the introduction of 2 ounces of olive oil into the mouth shortly after the patients reflexes have become re-established.

*Active Treatment* consists primarily of immediate lavage of the stomach, early, repeated and prolonged. No matter how piteously the patient may beg to be let alone *it must be done.* There is no existent contraindication to its use. Any tube which can be most conveniently passed into the stomach is the right one, and any non-toxic solution the correct one. Warm water to which has been added sodium bicarbonate, 1 dram to the quart, is perhaps the most efficacious. The lavage must be continued until the return is clear and be repeated at the first evidence of redistention, continued nausea or a return of regurgitation. Stimulating enemata, such as turpentine, milk and molasses, or alum should then be employed. These procedures may alone be sufficient to relieve the condition, if the paresis has been of short duration, but there is a certain class of patients who are more resistant, in whom the stomach refuses to empty itself and the peristalsis of the bowel does not become re-established.

*Medical Treatment.*—Heretofore we have used in these cases injections of eserine sulphate or of salicylate, grain 1/40, repeated as necessary, with favorable results eventually in some cases after prolonged discomfort on the patient's part. In certain recent cases we have employed an intravenous injection of 20 to 40 c.c. of hormonal (which is a peristaltic hormone discovered lately by Zuelzer). Thus far our experience in its use has been most fortunate. Those, however, who have employed it more extensively particularly in clinical work (chronic obstipation) report that in approximately 25 per cent. of the cases it fails to act. However, if it is going to act its results are quickly appreciated and it seems to be fairly innocuous when properly administered. In some patients with chronic bowel atony and habitual constipation the results have been most remarkable, but seem rather evanescent.

Before employing this agent in cases of post-operative gastroenteric paresis, occasion was taken to verify by animal experimentation the efficacy of this peristaltic hormone, for which purpose rabbits were used. By injecting intravenously, amounts varying from 3 c.c. to 7 c.c., we were able to conclusively demonstrate that a physiological peristalsis was evoked, varying in degree, however, in different animals. In control of these observations, eserine salicylate, grain 1/130, was similarly injected intravenously, from which administration, spastic contractions of the intestine were noted to occur, which incisures remained for some time with but little propulsion of the bowel contents in some instances. Certainly its action was in no way a reproduction of physiological peristalsis but seemed to affect more the circular musculature while that resulting from hormonal appeared to affect only the longitudinal fibers.

Under no circumstances whatever should any cathartics be employed until *after* the stomach has been thoroughly evacuated, as the retained secretions become after a very short time exceedingly toxic, and if success should crown the efforts of the surgeon to effect a large bland smelling green or grumous stool, it has been our experience, which has been corroborated by others, that while felicitations and congratulations are being indulged in, return to the bedside will be rewarded by seeing the patient die suddenly as the result of intestinal absorption of its toxic contents.

Instillation of warm saline solution per rectum by the drip method is frequently an important adjunct, especially in assuaging thirst, as but very small amounts of water should be allowed by mouth even after the condition is relieved, and the diet for several days should be practically dry.

*Treatment by Posture* has been advocated by many, exclusively by some, particularly those upholding the mechanical theory, while others have combined it with lavage. The knee-chest position or ventral decubitus will, however, not appeal to most surgeons in the treatment of immediate post operative cases, and the patient will most certainly object.

*Operative Treatment* although still undertaken by some had best be discontinued as its results thus far show a mortality of practically 100 per cent., and when one stops to consider what the condition is that is being dealt with, they will realize that the reason for their failures is because they are adding insult to injury.

## WARMING ANESTHETIC VAPORS NEITHER USELESS NOR FALLACIOUS.*

By RAYMOND C. COBURN, M.A., M.D.,
NEW YORK.

In a recent article Cotton and Boothby, after reporting the temperatures observed in three experiments and in one clinical case, make this deduction: "These experiments seem effectively and permanently to dispose of the argument for the necessity of artifically warming the respired mixture."[1] Still more sweeping is the caption under which this article appears, "The Uselessness of Warming Anesthetic Vapors." Seelig likewise reports temperature records of some experiments, and purports to show "The Fallacy of Warmed Ether Vapor."[2] It is the purpose of the writer to show by the self same experiments that these conclusions are unwarranted and unscientific; that artificially warming anesthetic vapors has well established scientific merit, both theoretically and clinically; that the real and only fallacy lies in the deductions made by these writers from their own experiments; and that in the only clinical case reported by these adverse critics the very anesthetic vapors they administered were artificially warmed.

First, a word as to nomenclature: "The closed or so-called vapor method"[1] of administering ether would better be and is here called the insufflation† method, as this term is accurate and completely descriptive. The term insufflation method is used in its broad significance and is not to be confused with the intratracheal insufflation method, which is a subdivision. The closed method is synonymous with the rebreathing method, whereas there is usually no rebreathing in the insufflation method, although there may be. The term vapor method is misleading, as all respired anesthetics are administered as vapors, consequently they are all vapor methods.

Cotton and Boothby show that in the insufflation method of administering ether, when a 3-foot conducting tube is used, the vapor is slightly below room temperature when respired by the patient.[1] This method though, admirable as it is, is used in only a small percentage of ether administrations; a most liberal estimate would be 1 per cent. What, then, warrants the unqualified caption "The Uselessness of Warming Anesthetic Vapors"? Are the 99 per cent. of ether administrations to be ignored?

Certainly the great preponderance of other methods deserves some consideration, especially as the thermal condition varies with the method.

In the open drop method, which is most generally used, the inspired vapor is admittedly cold; temperature records show that it approaches and even reaches the freezing point in an operating room temperature of 75° F.[3 4 5] Seelig, in his experiments, shows that by the time this cold vapor reaches the lungs it is warmed to body temperature.[2] But the fact that the vapor is warmed to body temperature by the time it reaches the lungs nowise warrants the conclusion that, therefore, the cold ether vapor, *per se*, is not injurious to the patient, for this evades the whole matter at issue. What is the effect of the cold vapor before it is warmed, and what is the source of the heat that warms the cold vapor? Surely there can be no doubt as to the proper answer to these questions.

Cold ether vapor is more irritating than warm. Therefore it is a scientific, as well as a clinically observed fact that cold ether vapor causes more irritation of the upper air passages than the warm. The injury to the cells thus produced and the augmented secretion of mucus both increase the liability of postoperative infection, for the patient's resistance against infection, at this particular time, is considerably lowered by this anesthetic. Besides, the energy required to warm the cold vapor is abstracted directly from the patient's vitality. Why should the patient be forced to sacrifice any vitality needlessly, at such a critical time?

In order to prevent the unnecessary irritation of the admittedly cold ether vapor by the open drop method, and the needless extraction of heat from the patient in warming this cold vapor to body temperature before it reaches the lungs, I devised a special inhaler and a small electric heater, which I have previously illustrated and described.[4 5 6] This is the only apparatus, to my knowledge, that delivers to the patient ether vapor at body temperature in the open drop method. This delivery to the patient of warmed ether vapor is not a presumed fallacy, it is an established fact, and whether or not it is a useless procedure is better attested by those who use this method of administration. Quoting T. W. Kilmer, of this city: "The induction is smoother, cough and laryngeal spasm are hardly ever seen, and I think the patient is in a better physical condition, especially after a long anesthesia, when the above open drop method of warm ether anesthesia has been used."[7]

In the rebreathing method of administering ether, which was introduced by Clover nearly forty years ago and which is in quite extensive use, there is an artificial warming of the respired vapor to a pronounced degree. The practical value of this feature has long since been recognized and is mentioned by many writers.

Gwathmey has clearly shown that anesthetic vapors administered at their normal or original temperatures are much more toxic than when administered warm, and this is the essence of the whole matter.[8]

It is a curious yet significant fact that Cotton and Boothby, in attempting to show the uselessness of artificially warming anesthetic vapors, artificially warm all their own vapors.[1] After the anesthetics are vaporized they conduct the vapors through a 3-foot rubber tube, and this, by their own experiments, warms the vapors so that by the time they reach the end of the tube, or the patient's respiratory passages, they are only slightly below room temperature. This tubing, while designed for conduction only, acts as a warming device as effectively as if designed primarily for this purpose, and the warming, being accomplished through mechanical means, is therefore artificial. Even the temperature of the operating room in this climate is, the greater part of the time, maintained artificially. The error of overlooking the fact that by this method all the vapors are artificially warmed might be of little importance were it not for the erroneous and misleading conclusions that have been deducted and applied generally.

*Read before the New York Society of Anesthetists, Feb. 13, 1913.

† "A forcible blowing."—Standard Dictionary.

It is universally conceded that the crucial test is the regular operating room experience, and fortunately these writers report the temperature observations in such a case. The anesthetic was nitrous oxide and oxygen with a small amount of ether. After one hour's administration they report "the temperature on inspiration was 34° C." (or, in other words, it was 16° F. *above* the temperature of the operating room. This is artificial warming with a vengeance! Either the temperature records are incorrect or other artificial means were used in warming the respired mixture so much above the temperature of the surrounding media. It would be contrary to the laws of physics for the temperature on inspiration to be so much above that of the operating room unless further artificially warmed. Rebreathing is the explanation, but in this there is the additional warming of the respired mixture.

These experiments and clinical case show that in the rebreathing method of administering nitrous oxide a special heating device is not needed, but Gatch had previously established this point, as will later appear. In the insufflation method with ether Cotton and Boothby show that the temperature of the vapor when it reaches the patient is 12° F. higher with an efficient heating apparatus than when it is not used. The only questionable proposition in the whole matter is whether, in this particular method, the vapor is delivered to the patient at a higher temperature when a special heating device is used, as without it there is always artificial warming of the vapor anyway as it passes through the tube leading to the patient. Their own experiments more than prove all previous claims of achievement in this respect.

Let us not, however, be confused by these recent experiments concerning the long established laws of physics or by the discussions as to whether, in the insufflation method of administering ether, the temperature of the vapor as it reaches the patient is affected by a special heating device or not, lest we miss the merits of the question as to whether warm anesthetic vapors are beneficial or useless. A special heating device in this particular method may be entirely useless and yet warm anesthetic vapors be distinctly beneficial. There is always an artificial warming of the vapor in this method, and whether by a special heating device this warm vapor can be delivered to the patient at a still higher temperature, is quite aside from the question as to whether warm anesthetic vapors are beneficial or not. The latter is a general proposition, and does not depend upon how much the vapor is warmed in any particular method, provided only that it is warmed to an appreciable degree. The essential physics of this matter is very simple: anesthetic vapors are primarily cold, but may be delivered to the patient in temperatures ranging from the original to body temperature, or even higher. It matters not whether you call the process warming the vapor, effective vaporization, or any other name. The constant, conspicuous, and demonstrable physical feature is that the temperature of the vapor is artificially raised, and that is all that is embraced in the term "warming anesthetic vapor."* That does not even imply, much less require, that a special heating appliance be used, or that the vapor be delivered to the patient above room, or any other specific temperature.

*This completely corresponds with the definition of warm, namely, "to communicate a moderate degree of heat to," as given by Webster's International and the Century Dictionaries; also with that of the Standard Dictionary, "to communicate warmth to; to raise the temperature of."

In the methods brought into question by these adverse critics they, themselves, show that the vapors are warm, consequently we may now drop the physics and study the physiology. To do this best, let us leave their laboratory and go to the operating room of Johns Hopkins Hospital.

Davis shows that the difference in the loss of body temperature under similar conditions of patients, operations, etc., is quite marked, with only different temperatures of ether vapor.[9] In ordinary procedure when ether was administered by the open drop method the loss of body temperature averaged 1.02° F., and when the vapor was warmed the loss averaged only 0.29° F., and in extensive operations involving much exposure the difference in loss of body temperature averaged 1.2° F. in favor of the warm ether vapor. As far as this discussion is concerned it makes not the slightest difference whether this vapor reached the patient at room temperature, nearly room temperature, or nearly body temperature. The essential points are that the vapor was warmed, and that when the warm vapor was used there was a decided beneficial effect.

As regards warm nitrous oxide vapor Gatch says: "The carbon oxide is not the only product of expiration the effect of which must be studied with regard to rebreathing. The heat of the exhaled gas has an important action. Normally the body loses a large amount of heat in the expired air. This loss is prevented by rebreathing. Therefore there is a rise in body temperature. This I have almost always found to be over half a degree in anesthesias of thirty minutes or more. During an administration of three hours the temperature arose 1.3 degrees. Rebreathing is thus a most effective method of heating the gases, which are cold on being freed from their cylinders."[10]

The above are extracts from the official clinical reports from Johns Hopkins University records, not laboratory experiments—clinical reports covering hundreds of cases, clinical reports clearly showing a marked conservation of the patient's vitality when the vapors are administered warm. In other words, there is an abundance of authentic, clinical evidence to show that warm anesthetic vapors are of decided benefit to the patient, and are, consequently, conducive to ultimate recovery. The practice of warming anesthetic vapors stands the test of the most searching scrutiny, being neither useless nor fallacious, but well serving the best interest of the patient.

# THE LUETIN SKIN TEST IN THE DIAGNOSIS OF SYPHILIS.*

By A. G. RYTINA, A.B., M.D.,

BALTIMORE, MD.

ASSOCIATE IN GENITOURINARY SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS.

After the discovery of the *Spirochæta pallida*, several observers attempted to obtain a cutaneous reaction for syphilis by applying extracts prepared from syphilitic tissue to the skin of syphilitic patients.

For this purpose, Tedeschi employed watery extracts of chancres. Nobl watery and alcoholic extracts of early lesions, rich in spirochetes. Ciuffo made use of glycerin extracts of congenitally syphilitic organs; he obtained more marked reactions in healthy individuals than in luetics, whereas Nobl's results were entirely negative. Nicholas, Favre, and Gauthier by intradermic applications of syphilin (a concentrated glycerin extract of liver rich in spirochetes) succeeded in producing nodular infiltrations, while on the other hand, Bruck, Bertin, and Bruyant obtained opposite results. Neisser and Bruck found that a similar reaction could be produced with a concentrated extract of normal liver, as with a syphilitic extract.

More recently, Fontana carried on a series of similar experiments with syphilin, sodium glycocholate, lecithin, and extract of syphilitic heart. Syphilin gave positive reactions in twenty-seven of fifty syphilitics (53 per cent.) Two of sixteen non-luetics (12½ per cent.) also gave positive reactions. In forty of these, the Wassermann reaction was done at the same time, with a positive result in thirty-four, against nineteen positive syphilin reactions. The positive reactions were characterized by infiltrations at the site of injection, varying in size from a grain of wheat to a grain of corn.

As can be seen, the work of these observers, while in some respects encouraging, is on the whole contradictory. These discordant results are not surprising, when we realize that the extracts injected were made from syphilitic tissues, which contained in addition to a small number of the spirochetes secondary organisms and a larger amount of body fluid, which not only diminished the concentration of the extract, but modified its activity and rendered it innocuous, as injections of the preparations in animals would not produce syphilis. Von Pirquet predicted that it would be possible to make the diagnosis of syphilis by means of cutaneous and subcutaneous inoculations, as soon as the syphilitic virus could be obtained in pure culture without admixture and in sufficiently concentrated form. How well von Pirquet's prediction has been fulfilled Noguchi's discovery indicates.

Several investigators lay claim to have grown the *Spirochæta pallida*. In 1907 Levaditi, Yamanouchi, and several others, noted that the *Spirochæta pallida* remained motile for weeks in a collodion sac filled with serum of a monkey and injected into the peritoneal cavity of that animal. Schereschewski, in 1909, claimed to have grown an impure culture of the *Spirochæta pallida*, by employing gelatinized horse serum as a culture medium. In 1910, Bruckner and Galesco, and Sowade in 1911, reported the successful inoculation of rabbits by employing impure cultures produced by them. In 1909 Mühlens, by modifying Schereschewski's technique, succeeded in isolating a pure and luxuriant growth of spirochetes for one generation. Hoffmann, in 1911, working with Mühlens, also reported the growth of the spirochetes in pure culture. In the impure cultures of Bruckner and Galesco, and Sowade, the further growth of the spirochetes was impossible. The objection could not be removed, therefore, that the inoculations were due to contaminating organisms. The cultures of Schereschewski, Mühlens, and Hoffmann were non-pathogenic. All the above observers based their claim for the successful growth of the spirochete upon the morphological characteristics alone. Noguchi has shown that it is often impossible to differentiate the *Spirochæta pallida* from *S. dentium* by the morphology, but certain cultural requirements are essential before the differentiation is absolute. Noguchi lays down the following dicta in identifying a cultivated spirochete with *S. pallida:* (1) The spirochete must be morphologically correct. (2) It must not produce a putrefactive odor. (3) It requires the addition of fresh tissue for growth. (4) Its extractor emulsion must bind complement with the immune serum (rabbit is preferred) produced by repeated injections of the tissue pallida (to be obtained from syphilitic orchitis of rabbits). (5) Its extract of emulsion must give an allergic reaction in certain cases of syphilis. (6) It should be pathogenic. The last requirement is highly important, but we can not exclude the possibility of the organism still being the pallida, even if it is avirulent, as long as it fulfills the other five points, because it is not impossible that a strain of pallida may become attenuated in cultivation.

Noguchi has succeeded in cultivating six different strains of *S. pallida* from the orchitis material of rabbits and seven directly from chancres, condylomata, and skin papules of human subjects. The methods used are different, according to whether the pallida is cultivated from the orchitis of rabbits or directly from man. After obtaining the pure cultures of *S. pallida,* Noguchi made repeated intravenous injections of pallida antigens into rabbits for several months and then giving them a month's rest, tested them with an extract, which was termed luetin, to see if they could not be made allergic to the extract of the pure pallida. They all gave a very decided reaction, characterized by marked inflammation, some leading to pustulation. While he was still working with animals, Professor Welch suggested that he try it in human syphilis.

*Preparation of the Cultures for the Cutaneous Reaction.*—Briefly stated, luetin is nothing but an emulsion of dead *S. pallidæ* and the control is composed of the same constituents as the luetin, minus the pallida. In order to secure a polyvalent antigen, six different strains of the spirochetes are employed. Noguchi prepares it as follows: Cultures are allowed to grow for periods of six, twelve, twenty-four, and fifty days at 37 C. under anaerobic conditions. One is grown in ascitic fluid to which a piece of sterile placenta has been added and the other in ascitic fluid-agar also containing placenta. The lower portion of each solid culture in which a dense growth occurs is cut out and the tissue removed. The agar columns which contain innumerable spirochetes are then carefully ground in a sterile mortar, and the resulting thick paste is gradually diluted by adding little by little the fluid culture,

*Read at the meeting of the Baltimore City Medical Society October 18, 1912.

which also contains an enormous mass of organisms. The dilution is continued, until the emulsion becomes perfectly liquid. The preparation is next heated to 60° C. for sixty minutes in a water bath and then 0.5 tricresol added. When examined under the dark ground illuminator, many dead pallida per field can be seen. Cultures made from this suspension remain sterile and with them no infection can be produced in the testicles of rabbits. The suspension is kept in a refrigerator when not in use. In order to ascertain, if the reaction produced with the suspension might not be due to inoculation of the tricresolized culture medium alone, it is necessary to prepare a similar emulsion with uninoculated media to be used for control purposes.

Technique and Method of Application.—To the luetin at the time of application, an equal amount of normal, sterile salt solution is added and the injection is made intradermically in the right arm, previously well sponged with alcohol. The amount injected, with a very fine needle, .07 c.c. for adults, .05 c.c. for children, is accurately measured and the proper application evidenced by a small, raised, blanched papule, which subsides in about ten minutes. The control is prepared and injected in the same manner in the left arm. For the control, I employ a one cubic centimeter tuberculin syringe and for the luetin a half cubic centimeter tuberculin syringe. In the latter, the graduations are wider, making measurements easier and more accurate. Further, it avoids any possible confusion between the two. Separate sterilized pipettes, tubes, etc., are kept for the luetin and control, thereby preventing contamination.

Up to the present time we have given 150 to 200 luetin injections, but in the present study we are only including such cases as have been followed to a positive termination or watched over a period of at least thirty-six days. The number of such cases is 117.

*Description of the Reactions.*—Noguchi's apt classification is followed.

Normal or Negative Reactions.—After about twenty-four hours in about one-half of my normal or negative cases, nothing except a slight erythema at the site of injection appeared. In forty-eight hours, this had practically disappeared. In the other half after twenty-four hours, there was a definite raised, indurated, papular formation, surrounded by a more or less marked erythematous zone. The beginner in luetin work will at once predict a positive reaction for this patient. This gradually recedes, however, so that by the fifth day, with the exception of a slight pigmentation, nothing more may be noted. On this account reactions appearing at this early period have no diagnostic significance. They are due to the irritation caused by the injection of the foreign material. In a smaller group of cases, however, an eruption presenting the following characteristics appeared. After twenty-four hours, a small, raised, red, indurated papule appeared surrounded by a definite erythematous zone. After forty-eight hours the erythematous zone would disappear, leaving the papule, which would persist as long as two weeks or more, showing only a change in color from red to dark red, then a purplish hue. No pain or itching was complained of. In my early experiences I was in doubt as to the correct interpretation of these lesions, particularly as they were in types of syphilitics in whom the positive reaction is found with the greatest frequency, viz., tertiary lues. At the time I recorded these as doubtful positive reactions. Later on some of these developed at the site of the doubtful reaction lesions of the torpid form of reaction, to be described later. In the beginning of my work most of the patients injected were syphilitic patients and in order to elucidate this point further and determine if a similar doubtful reaction could be produced in non-luetic individuals, I injected twenty-eight persons who were thought to be normal or suffering with other diseases than syphilis. The experience in these cases showed that in none was there after four or five days anything except a slight pigmentation of the skin to indicate the site of the former injection. As Noguchi does not mention this phenomenon I am impelled to record these eruptions as mildly positive reactions.

Positive Reactions.—Papular Form.—Twenty-four to forty-eight hours after the injection a large, red, raised, indurated papule, 5 to 10 mm. in diameter, appears. The papule may be surrounded by a zone of erythema which may also appear slightly edematous. The papule, instead of slowly receding, gradually progresses for the next two or three days, becoming dark or bluish red, when it gradually subsides, disappearing completely within seven to ten days. Evidence of it may persist, however, as long as two or three weeks. In our series the papular form of eruption was noted three times in secondary lues, six times in tertiary, and once in parasyphilis. Total ten.

Pustular Form.—In this form for the first four or five days the lesions will assume the papillary type. After this the surface of the indurated papule will become capped by small vesicles and a beginning central softening will be noted.

After a short time the papule becomes definitely pustular, containing at its apex at first a semi-opaque serum, which later becomes definitely purulent. Pain and itching more or less severe may be complained of. This later ruptures, either spontaneously or by rubbing against the sleeve, leaving an opening surrounded by the indurated margin of the pustule. The gap left by the discharge of pus becomes quickly covered by a scaly crust, which falls off in a few days. The induration gradually subsides, with little or no scar formation. But a pigmentation remains, which may persist for several months. Some of the pustular lesions, instead of breaking down, present a small, central, soft, red, fluctuating mass which is gradually reabsorbed. The number of cases of this type in our series was one in primary, two in secondary, nine in tertiary, and three in parasyphilis. Total fifteen.

Torpid Form.—In this form, the injection site fades away after three or four days, so that the case is recorded as a negative reaction, when suddenly it reappears and progresses to papular or pustular formation, following the course of the types described above. Noguchi regards this type as a rare form, but I have seen it four times in secondary, five times in tertiary, once in latent, and once in hereditary syphilis—total eleven, or 9.3 per cent. of cases recorded. The cause of this rather large percentage of the torpid form in our series is due, I believe, to the neosalvarsan injections, which often follow the luetin test. In one case it did not appear until thirty-six days after the injection. The earliest it appeared was eight days, the average time being fifteen days. On this account I do not consider any injection negative unless the patient has been observed for a period of at least thirty-six days. My plan is to make daily observations for

five or six days, and if at this time the reaction is negative the patient is instructed, if he is an ambulant case, to report every few days, unless he notes the site of injection again flaring up when he is to report on the same day. I have seen no constitutional reaction, excepting a slight rise of temperature, 99° to 100° F., and a slight transient headache. In connection with the various types of eruptions appearing in positive cases, it is interesting to note the changes appearing at the site of the control injection. In fourteen cases the control site evidenced changes of the same character, as on the opposite side, viz., a papular or pustular formation. The lesions are usually, but not always, of a similar character as on the opposite side, although in five cases they were more pronounced than at the site of the luetin injections. One of these, a case of tertiary syphilis, presented a lesion characterized by a broad, rounded, erythematous zone, in the center of which was a sharply circumscribed, hemorrhagic pustule, about the size of a large pea. A few days later, he developed a similar reaction on the right or luetin side. The control side ruptured, discharging a dark grumous material, whereas that on the luetin side was reabsorbed without rupture. This same phenomenon has been observed by Wolfsohn and Robinson. The cause of the reaction on the control side is due to the peculiarity of the skin of spyhilitics, especially tertiary syphilitics, to be prone to infection and traumatic irritation. This is a fact often commented upon by dermatologists and surgeons. For an explanation of this phenomenon Finger advanced the theory of superinfection. He presupposes that, following the trauma, owing to a point of least resistance being present, the syphilitic virus is deposited there and produces the lesion. On the contrary, Neisser after failing to find *Spirochæta pallida* in the lesions, attributed the cause to a peculiar pathological condition of the skin of syphilitics, which he has termed "Umstimmung." That this condition exists is quite evident, as in none of my non-luetic cases have I once observed such a reaction. But the most interesting cases of this character were those, numbering two, in which a typical reaction appeared on the control side, with a negative reaction on the luetin side. Care was taken to avoid contamination, injection into the wrong arm, etc. The theory of infection was eliminated as a causative factor on account of the time of appearance, eight and seven days respectively, and the papular form in one, typical in every way. I attributed the cause of the reaction in these cases to the state of "Umstimmung." To determine, however, this point more fully, twenty-five persons who were either normal or suffering with some disease other than syphilis were injected in both arms with the control only. The reaction was negative in all.

*The Cause of the Reaction.*—The reaction depends upon the production of that peculiar state, known as allergy, anaphylaxis, or Theobald Smith phenomenon, about which so much has been written in the last few years. Allergy is the peculiar state of reactivity of the system of individuals, characterized by a specific hypersensitiveness to the protein content of certain pathogenic organisms, serums, food, etc., after they have become sensitized. This sensitization develops only when a certain time is allowed to elapse between the introduction of the foreign protein and the first inoculation. It is impossible to produce the allergic state if the inoculations are regular and steady. It is most likely to occur, therefore, in those patients, suffering with diseases of the more chronic type, in which the organisms, etc., have had time to undergo the changes, either spontaneously or by the modifications produced by the therapeutic interference or by the substances developed in the infected host, either or all of which may be necessary to produce the state of sensitization. It is absolutely specific in its nature, and is so delicate that one-millionth of a cubic centimeter of a 5 per cent. solution of a three times crystallized egg albumin, or one-thousandth of a millionth of a gram of protein, will sensitize a guinea pig enough so that distinct and typical symptoms are produced after a second injection of the same material, while one-fifty-thousandth of a cubic centimeter of solution containing one-millionth of a gram of protein sensitizes fatally. (Wells.) Some of the best examples of the allergic phenomenon are the symptoms of intoxication which sometimes ensue upon a second injection of diphtheria antitoxin, Koch's tuberculin test, von Pirquet's cutaneous test, Moro's percutaneous test, Calmette-Wolff-Eissner's test, the mallein test in glanders, vaccinia, etc. Theoretically one would not expect to find the allergic condition present in the early congenital and early acquired cases, because the spirochetes and the infected host have not as yet undergone the changes necessary to produce sensitization. But in the later stages we ought to find it present in a larger percentage of individuals. These theoretical suppositions are well borne out by the practical results reported.

*The Value of the Reaction.*—That the luetin reaction is a very valuable addition to our diagnostic armamentarium is unquestionable. It is quite true that in the primary stage we can easily demonstrate the *Spirochæta pallida,* and the secondary stage presents evident lesions or a positive Wassermann reaction, making application of the test superfluous. But in the late stages of the disease, especially when it involves organs remote from the surface, *e.g.* gumma of the internal organs, it baffles the diagnostic acuity of the most skilled. It often happens, and especially after specific treatment, that the Wassermann reaction is negative in these cases, thereby adding to the obscurity. It is in such type of cases that the luetin reaction is about 100 per cent. positive. Furthermore, the administration of mercury does not temporarily inhibit the phenomenon as it does the Wassermann reaction. Then, the ease with which it may be carried out must commend itself. Just how much importance can be attached to the test for determining the cure of syphilis cannot at this time be answered with certainty. According to Noguchi the allergic condition of the skin of syphilitic patients persists as long as the infecting agent still survives somewhere in the body, and it requires a most energetic treatment to remove it. Following the complete eradication from the system, the allergy after a certain time must also disappear. In animal experiments the luetin reaction no longer appears after several months, Noguchi mentions two tertiary cases in which, following salvarsan injections, the Wassermann reaction became and remained negative. The luetin test, made eleven and eight months respectively after the treatment, was negative. This would seem to indicate that cured syphilis, unlike healed tuberculosis, will not give a positive reaction after a certain time. As of prognostic value in determining a cure may be recorded the patient of Wolfsohn, in whom one year before admission, 0.6 gram of sal-

varsan was given. The Wassermann reaction was negative both with blood serum and cerebrospinal fluid. The luetin test was, however, positive. There are cases, however, in which the disease persists in spite of treatment and the patients do not give a positive reaction. This class of cases, according to Noguchi, shows undoubtedly an unfavorable prognosis. At times we have seen a negative luetin, notwithstanding marked clinical symptoms and a positive Wassermann reaction, but following therapeutic interference, the opposite condition would be produced, viz., a negative Wassermann reaction and a marked positive luetin.

*Comparison of the Luetin Test with the Wassermann Reaction.*—A comparison of the luetin injection with the Wassermann reaction gave us the following results: Primary cases, two. Luetin reaction positive in one, negative in the other. Wassermann reaction positive in one, doubtful in the other. *Spirochæta pallida* demonstrated in both. The positive luetin had the doubtful Wassermann reaction, while the one with the negative luetin had the positive Wassermann reaction. Secondary cases: Luetin positive in nine, negative in eight; Wassermann reaction positive in nine, doubtful in one, negative in seven. Six of these seven negative cases had received previous salvarsan or neosalvarsan treatment, mostly by the multiple method of dosage, which we have adopted. This, in my opinion, is the cause of the large percentage of negative Wassermann reactions in these cases. In these seven cases with negative Wassermann reactions, the luetin was positive in three, negative in four. Tertiary cases numbered twenty-three. Wassermann reaction positive in eleven, negative in nine, not recorded in three. Of these, three were doubtful cases of tertiary syphilis. The luetin reaction, on the other hand, was positive in twenty, negative in three. Noguchi maintains that the luetin is 100 per cent. positive in active tertiary cases and 94 per cent. positive in tertiary cases without symptoms. Of my three tertiary cases with negative luetin reaction two had no clinical symptoms, were in excellent health, and the diagnosis was made on a history of chancre many years ago and a positive Wassermann reaction. The third patient had severe tertiary ulcerations in November, 1910, which resisted a most vigorous mercury and potassium iodide treatment. Following salvarsan treatment, his lesions receded and his Wassermann reaction has since been persistently negative. Two negative luetin reactions convince me more than ever that I have cured his malignant syphilis. Similarly in another case in the secondary period with no symptoms a persistent negative Wassermann reaction for nearly two years after salvarsan and two negative luetin reactions enforces the belief that we *do* sometimes cure syphilis by salvarsan injections.

Congenital Syphilis.—Noguchi claims that after congenital syphilis has existed some time, the luetin test is practically 100 per cent. positive. We have applied the test to only five cases of congenital syphilis, but as they were, excepting one, in very small children who would not remain quiet, the injections were subcutaneous rather than intradermic. As I feel confident that after subcutaneous injections the test can not be relied upon I have discarded these four from our series.

Parasyphilis.—Seventeen cases. Wassermann reaction positive in four, negative in three, not recorded in eight, doubtful in two. In these luetin was positive in five, negative in twelve. Noguchi statistics show that the luetin test is about 80 per cent. positive in parasyphilis. In our series the luetin test was positive in five of seventeen cases, or about 30 per cent. Fourteen of our parasyphilitic cases were inmates of Bay View Insane Department, in the majority of whom the history of syphilis was indefinite and the Wassermann reaction test not made. This accounts for the large percentage of negative luetin reactions in these cases. In the three parasyphilis cases seen in our clinic, in which the history of syphilis was certain and the Wassermann reaction positive, the luetin reaction was positive in all. These results again aid in putting tabes dorsalis, etc., in the category of syphilis, to which we now know they rightly belong.

Latent Syphilis.—In this class I have put a patient with sexual neurasthenia, who was injected merely as a control, but who gave a very decided reaction. His Wassermann reaction was negative. Careful inquiry failed to elicit any history of chancre or secondaries. By latent syphilis, however, is usually meant the type seen in apparently healthy mothers, who give birth to syphilitic children. According to Noguchi these cases give a 100 per cent. positive reaction and as the Wassermann reaction in this class of cases is only 40 to 50 per cent. positive we can again see the great value of the luetin reaction. This again aids us in explaining why she is subject to Colles' law, *i.e.* the apparently healthy mother of a syphilitic child cannot be infected by that child.

Doubtful Cases.—Number four. Wassermann reaction and luetin reaction negative in all. Two of these patients were suffering with severe syphilophobia, and I believe the application and study of the test caused sufficient psychological influence to effect a cure.

To recapitulate: In primary and secondary syphilis the luetin test is less constant than the Wassermann reaction, but in tertiary, latent, and congenital syphilis, and parasyphilis it is much more positive and therefore of greater value than the complement fixation test.

Control Cases.—For purposes of control the luetin reaction was applied to twenty-eight persons who were either normal or suffering with some disease other than syphilis. The luetin test was negative in all. Twenty-five non-luetic cases as already mentioned, received injections in both arms of the control only. All reacted negatively.

*Conclusions.*—1. The luetin is entirely harmless.

2. It is specific.

3. While the technique is comparatively easy and could be still more simplified by putting up in ampoules the full dose, ready for use, it requires a little practice and experience to make the application properly and interpret correctly the mild form of positive reaction.

4. It is mostly negative in primary and secondary untreated cases, but shows a large percentage of positive reactions, in such cases, receiving previous treatment.

5. In congenital, latent, and tertiary syphilis it is practically 100 per cent. positive. In parasyphilis it is positive in a large percentage of cases.

6. The luetin test is less constant than the Wassermann reaction in primary and secondary syphilis, but possesses greater value as a diagnostic agent than the latter in tertiary, latent, and congenital cases and parasyphilis. Furthermore it possesses greater prognostic significance than the Wasser-

mann reaction in determining when syphilis is cured.

I wish to thank Dr. Noguchi for his generous supply of luetin and control, Drs. Simon, Ireland, and Judd, for the Wassermann tests, Dr. Hanna for much help in the application of the tests and study of the cases and Dr. Truitt for the cases studied at Bay View.

Professional Building

## OCCUPATION AS A THERAPEUTIC MEASURE.*

By W. R. DUNTON, Jr., M.D.,

TOWSON, MD.,

PHYSICIAN TO THE SHEPPARD AND ENOCH PRATT HOSPITAL.

Occupation as a remedial agent has been used for mental cases for a great many years. The Friends' Asylum, situated near Philadelphia, has records showing that as far back as 1830 certain measures were taken to establish occupation for the patients. In other hospitals for mental cases provision has been made to provide workshops, gardens, or other forms of employment for the patients, and at certain places definite classes have been given, usually with some form of art work.

During recent years this therapeutic measure has been used much more extensively and now a great many hospitals for mental cases have teachers, who are resident or in daily attendance, who give special classes in some form of handicraft and also give individual instruction where it is required.

Besides this, many institutions train all or part of their nurses in handicraft. At the Sheppard Hospital we give a definite course in handicraft, teaching merely the elements and leaving it to the nurse to develop any special technique which she may desire. This course includes certain forms of entertaining, such as card games or other forms of amusement; string work, paper folding and cutting, binding, crêpe-paper work, reed basketry, embroidery, leather work, wood work, and metal work—the purpose being to teach the elements of these forms of work and give a certain facility in the use of the necessary tools. An especial point, however, is made in teaching the pupils to utilize the various materials which they find ready at hand—such as wrapping paper and twine, which come around drygoods and from the grocery store, and various other simple materials.

It needs but slight consideration upon our part to realize how very much happier we are if we have some definite occupation, whether it be working, playing, or resting. The man who has nothing to do but amuse himself is usually one of the most unhappy and the man who is most happy and for whom we have the greatest respect is the one who is always busy with something and doing it well—no matter whether it be working or playing. In other words, the person who has a hobby or a number of hobbies has a safety valve which enables him to escape many worries, which the more idle person cannot.

Probably most of the members of the faculty have some hobby or other. It may be collecting engravings or postage stamps, playing golf or poker, or even playing in the faculty orchestra. At any rate he has a safety valve. He is much happier for it, but he probably does not realize how much this hobby may be to him, how much it does to keep him happy and contented, how much it does to rest him and keep him refreshed for his work. If one has considered this he probably realizes how much it means to him, and he has probably felt that if he could keep his patients in as good a mental condition as he is it would mean very much for their benefit. We all realize, I think, how much better the prognosis is if the patient is bright and cheerful, no matter how serious his illness, than if the patient is depressed, does not want to live, or says he is going to die. So that any means, such as occupation, which helps to keep our patients in this cheerful frame of mind is of undoubted value. The same is true, of course, of chronic diseases. The patient gets along better physically if he is in a bright and cheerful frame of mind. His ailments are not so constantly before him if he has some diversion, no matter what it may be.

It would be very easy to give numerous instances of how valuable as a therapeutic measure occupation may be, but it is hardly worth while to detain you longer by dwelling upon it.

Among those who have recently given a great impetus to invalid occupation is Miss Tracy, formerly a nurse connected with the Adams Nervine Hospital, near Boston, which treats mild nervous diseases, but principally cases of neurasthenia and psychasthenia, who, in her book entitled "Invalid Occupation," has given definite directions as to kinds of occupation to be used for different cases. In this book Miss Tracy first describes the methods of teaching and the necessary equipment, and in this part she dwells upon the desirability of utilizing what we ordinarily class as waste.

Recently Dr. Mary Lawson Neff, who is in charge of this work for the Massachusetts Board of Insanity, has shown me some very interesting objects which were made from waste—one of them being an article made from bone, which, of course, was a part of the kitchen waste.

Miss Tracy then takes up typical invalids and gives chapters upon the child of poverty and the child of wealth. She concludes the book with a list of occupations, which is really an index. The book is admirably illustrated and is excellent as an encyclopædia for those seeking occupation.

Recently Miss Tracy has given up her position at the Adams Nervine and is now doing nothing but teaching occupation work. It is practically impossible not to find in her book something which will interest everyone, although those who are experienced in the occupation of invalids and especially mental ones, know that at times it is extremely difficult to find an occupation which will take up their interest and which will engross their attention—for occupation to be successful this latter point is very necessary. The patient's attention must be engrossed. Things which are done in a mechanical manner are not beneficial. I had a most striking instance of this a number of years ago. A patient had been depressed and was convalescent and had taken up embroidery, with which she was quite familiar. She did not take much interest in it and would often pause in her work to look away and apparently indulge in self-communion with her gloomy thoughts. At this time I was very anxious to have some typesetting done and it occurred to me that possibly she could be taught to do it. This was done and there was an immediate improvement in the patient's condition. The work was new to her and required attention to do it properly, so that she had no time to indulge in gloomy reminiscences, and she made a fairly rapid recovery.

*Read at the semi-annual meeting of the Medical and Chirurgical Faculty of Maryland, November 12, 1912.

Besides the cheerfulness of which I have spoken, which results from occupation, our patients are much less apt to be restless, and in surgical cases we all realize what an excellent thing it is to have our patient lying quiet and not making the slight movements which may disturb the fracture or wound, whatever it is from which they are suffering. It seems useless to give further examples.

The form of occupation naturally will have to be adapted to the patient's individual tastes and the exigencies of the case; but string work, paper work, whittling, offer so many possibilities that it should not be difficult to find something in which the patient is interested. String work, of course, includes various forms of weaving, and patients can use the small frames, such as are used by school children, in a recumbent position. A visit to a store where kindergarten supplies are sold, or a consultation with some handicraft teacher, will surely furnish some occupation which will be of value.

## TEETH GROWING IN THE NASAL FOSSA.

By E. HARRISON GRIFFIN, M.D.

NEW YORK.

The nasal fossa has been described as the seat of the olfactory nerve and smell, also as an entrance of air to the respiratory tract. This is true in almost all cases, but the following report, supplemented by one that I chronicled years ago, would show that at times Dame Nature, that mother of our being, goes astray and tries to turn the canal into one with teeth, or a mouth, so to speak, but, tired at its first digression, it quickly goes back on its own natural lines and leaves a few cases like those I report below—freaks and abnormalities.

Mrs. A., age 54, entered my office one evening, complaining of a bad odor from her left nostril, attended with a profuse secretion of pus and matter. She had had the discharge for about two and one-half years, following the removal of one of her upper teeth, the one next to the wisdom tooth, so called; this wisdom tooth had been removed four years previously. The tooth was splintered in its removal and necessitated several visits to the dentist, who removed parts at each sitting. After the tooth had been thoroughly extricated, a hole was left in the alveolar process, through which there was a continuous discharge of pus into the buccal cavity. The tooth next to this one had been removed over ten years ago without any trouble. The continuous discharge of pus and matter from her nose and through the opening in the alveolar process brought her back again to the dentist. After an examination the dentist sent Mrs. A. to a surgeon, who diagnosed dead bone in her nose and operated upon it while she was under the influence of ether. The operation failed to give any relief. This was the condition which had existed for two and a half years, when she came under my observation.

An examination of the left nasal fossa showed this part to be covered with a pus secretion, very profuse in quantity and of a very penetrating odor. An examination by the probe showed something hard and grating to the touch. I explained matters to her and advised an immediate operation under cocaine. The patient was a little timorous at first, but soon gave her consent.

After the part had been well cocainized, I introduced a large strong pair of forceps and removed without much effort a perfect molar tooth. The crown of the tooth was clear of membrane, but the roots showed tissues still clinging to them, showing that the crown was uppermost in the nose and the prongs or fangs were seated in the floor of the nasal cavity.

The tooth was a counterpart of any ordinary tooth that might have been removed from the jaw. The crown was much decayed and was one large hollow. The discharge stopped immediately and in a few weeks the patient was discharged cured. I have since heard from Mrs. A., who reported that the discharge had permanently stopped.

This tooth unquestionably had been present in the nasal fossa for years, as the size, location, and the amount of decay showed.

Some thirty years ago I reported in the MEDICAL RECORD a case that I had shown at one of the sections of the Academy of Medicine. A patient, male about thirty-five, came under my observation at my throat and nose clinic at the Out-Door Poor Department of Bellevue Hospital. He had a perfect incisor growing from the floor of the nose into the nasal cavity. By tilting the nose upward and extending it with a speculum a perfect tooth could be seen, white in color, and as normal in size and contour as any that grows from a jaw. This patient suffered with a cleft palate. He had been operated upon years before when a child by the elder Mott, but the operation had failed to close up the space in the hard or soft palate.

These are rare cases, but they demonstrate that even Dame Nature at times goes astray or, feeling the monotony of turning out so many individuals of the same pattern, tries at times to improve, or to skylark at that very important vocation, the manufacturing of an individual.

55 WEST FORTY-SEVENTH STREET.

**Retention of Foreign Protein by the Kidney—A Study in Anaphylaxis.**—R. M. Pearce found that extracts of the kidneys of normal rabbits prepared one, two, three, and four days after the intravenous injection of egg-albumin and horse serum have the power to sensitize guinea pigs to a second injection of these proteins. The sensitization by first and second day extracts was constant and intense, that by the third day extracts was less marked and sometimes was not evident, and that by the fourth day extracts was only occasional, and when present was always weak. Comparative studies of the power of the blood, liver, and kidney to sensitize, indicate that this sensitization depends on the content of foreign protein in the circulating blood and not upon its accumulation or fixation in the tissues of an organ. This opinion is supported by other experiments in which the sensitizing power of the blood and of the extracts of unwashed kidneys was compared with the sensitizing power of extracts of washed kidney. The weak sensitizing power of washed kidney extract is taken as evidence that foreign proteins of the kinds used are not held in the tissues of the kidney, and if these results may be applied to nephrotoxic proteins, it follows that nephritis is not due to selective and persisting fixation of a protein by the renal cells, but is due to the action of such protein merely during the process of its elimination. In experimental acute nephritis of the type due to uranium nitrate, the power of sensitization to egg-albumin is prolonged for twenty-four hours, and in the chromate type for forty-eight hours, thus indicating that in nephritis, of the acute type at least, the elimination of a foreign protein is delayed. Attempts to study by the same methods the elimination of vegetable and bacterial proteins have failed.—*Journal of Experimental Medicine.*

## MONGOLISM AND ANCESTRAL AFFINITIES.

EVERY busy pediatric clinic sees annually a large number of cases of mongolian idiocy. The characteristic physiognomy makes the diagnosis a simple one. Those who have had ample opportunities of studying these cases in insane asylums and in institutions for feeble minded children have come to the conclusion that mongolism represents an arrest of development. C. Paget Lapage in his recent volume on "Feeblemindedness in Children of School Age" notes that many of these cases are the result of an exhaustion of the reproductive powers of one or both parents. In the majority of instances the mongol is the last child in a large family. Shuttleworth has pointed out that many of the characteristic features of mongols indicate an unfinished state; the poorly developed ears, the lax ligaments, the muscular hypotonia, the tendency to congenital heart disease, and the maldevelopment of the brain, are all signs of an arrest of development.

There is another theory, however, which regards mongolian idiocy as an instance of atavism, as a reversion to some primitive type of human structure. According to this view mongolism is of phylogenetic rather than of ontogenetic significance. F. G. Crookshank in a most interesting and scholarly thesis on this subject in the *Universal Medical Record*, January, 1913, regards mongolism as a form of infantilism of phylogenetic origin. The marked cases of this condition are stamped with simian characteristics, while the less pronounced cases resemble closely individuals of mongolian extraction. There is considerable evidence that there is an infusion of Mongolian or of Mongol-Malayan blood in many of the nations of Europe. The Finns, the Laps, the Turks, the Magyars, and the Basques are all of Mongolian origin. In the Celtic, Iberian, Melanochroic, or Mediterranese type of European a peculiar greenish complexion suggests a Mongolian heritage. Mongolian idiocy is regarded as a recrudescence of the dormant Mongolian element transmitted from the remote past. Crookshank believes that the "link between both the ancestral and environmental conditions that determine the growth of the organism must be sought for in the polyglandular balance." Mongolism is always first manifested during thymic life and tends to disappear when the other ductless glands develop their full functional activity. It is pointed out that mongoloids often have thymic attacks, and that the administration of thymus gland given in combination with thyroid produces a beneficial effect in cases without marked mental weakness or gross bodily defect.

## PURIFICATION OF WATER BY STORAGE.

THE question as to how best to supply a pure or comparatively pure water for human consumption is agitating the minds of health authorities everywhere. With regard to the most effective mode of rendering water safe, there is no decided unanimity of opinion. Some assert that slow sand filtration achieves this object best while others pin their faith to mechanical filtration. In some parts of Europe, notably in Paris, purification of water by ozonization seems to have met with a fair measure of success, while in the United States and in Canada chlorinization is a favorite method. A. C. Houston of London is a believer in the purification of water by storage, and at the meeting of the International Congress of Hygiene in Washington in September last read a paper in which he set forth his views. He discussed the purification of water by storage under three main headings: (1) sedimentation; (2) equalization, and (3) devitalization. The chief conclusions arrived at so far are as follows: Storage reduces (*a*) the number of bacteria of all sorts; (*b*) the number of bacteria capable of growing on agar at blood-heat; (*c*) the number of bacteria, chiefly excremental bacteria, capable of growing in a bile-salt medium at blood-heat; (*d*) the number of coli-like microbes; (*e*) the number of typical *B. coli;* (*f*) the amount of suspended matter, pigment, and ammoniacal nitrogen; and (*g*) the hardness.

Storage alters certain initial ratios, for example, (*h*) it reduces the number of typical *B. coli* to a proportionately greater extent than it does the number of bacteria of all other sorts; (*i*) the color results improve relatively to a greater extent than those yielded by the permanganate test. Storage if sufficiently prolonged, devitalizes the microbes of water-borne disease. Storage has a marked "levelling" or "equalizing" effect. An adequately stored water is to be regarded as a "safe" water and the "safety change" which has occurred in a stored water can be recognized and demonstrated by appropriate tests. The use of stored water enables a constant check to be maintained on the safety of a water supply antecedent to and irrespective of filtration. The use of stored water goes far to wipe out the gravity of any charge that a water supply is derived from polluted sources. The use of adequately stored water renders any accidental breakdown in the filtering arrangements much less serious than might otherwise be the case. The storage of a public water supply has obvious advantages and Houston's arguments in its favor have much to justify them, although storage on a large scale is open to the objection that it requires a good deal of space and is costly.

## TREATMENT OF RECENT INJURY BY MOBILIZATION AND MASSAGE.

Lucas-Championnière was the first distinguished surgeon to advocate and to practise the treatment of fractures by mobilization and massage. His disciples have so developed his method that it is now applied to other forms of recent injury, accidental and postoperative, in fact, to almost every class of case, in which massage forms an integral part of the treatment. According to James Mennell, who read a paper on the subject before the Medical Society of London, an epitome of which was published in the *Lancet*, February 1, 1913, the massage used consists of a slow, light, rhythmical stroking in the neighborhood of the injury, the movement being merely a "caress" and "almost resembling a mesmeric pass," while the actual site of the injury is scrupulously avoided. The mobilization must be regarded in the light of a therapeutic measure, the dose being meted out with care and accuracy. It consists of two elements, passive movement and active movement. When the dose of passive movement is being given the patient must be made to cooperate by actively relaxing the whole part. Failure to obtain this active relaxation, or the application of any other form of massage to the injured part is contrary to Lucas-Championnière's treatment, and absence of a satisfactory result in such circumstances must be ascribed to the practitioner and not to the treatment.

The main principle, or the underlying principle of the treatment is that "movement is life" and this axiom is carried into effect by massage which, however, is only the means of which mobilization is the end. The difference between the generally accepted forms of massage and this form is that the former aim at compulsion, whether of the blood in a given direction or of some movement, while the massage advocated by Lucas-Championnière aand his followers attempts, by its reflex action through the nervous system, only to restore the tone of the vasomotor system which has been disorganized by the shock of injury, and in like manner to combat the injury sustained by the nerves in connection with the injured part. Mennell is enthusiastic regarding the beneficial effects of the Lucas-Championnière method and strongly recommends mobilization with massage for nervous complaints of all descriptions, for postoperative arthritis, and for every kind of injury or strain. Indeed, he claims that in any case in which treatment by massage is indicated, mobilization and massage will yield results far superior to those reached by ordinary massage.

## Human Infection with the Bacillus Prodigiosus.

Interest in this microorganism has been centered chiefly in its use in conjunction with the streptococcus of erysipelas as one of the constituents of Coley's fluid. Although pathogenic to the lower animals, such as rabbits, mice, and guinea-pigs, it has not been known to cause infection in human beings. Parks has suggested that it may be the morbid cause in certain cases of diarrhea. The striking cultural characteristic of this bacillus is the marked coloration, varying from a pale pink to a deep blood-red, which it produces. An interesting case of human infection with this microorganism is reported by H. M. M. Woodward and K. B. Clark, in the *Lancet*, February 1, 1913. The patient was a man aged 24 who suffered from a chronic cough and expectorated from time to time, independently of the act of coughing, a pink stained sputum. This contained neither tubercle bacilli nor red blood cells, nor leucocytes, but produced on agar tubes a thick mixed growth of pink and white colonies. Subcultures from the white colonies showed a pure growth of the *Bacillus mesentericus*, while subcultures from the pink colonies showed all the characteristics of the *Bacillus prodigiosus*. A vaccine was prepared from this microorganism and was injected into the patient, as the result of which the latter's health began gradually to improve and his cough disappeared. The instructive point in this case is the fact that the expectoration of a pinkish sputum suggested a diagnosis of pulmonary tuberculosis, although no physical signs of this disease were present. The absence of red blood cells in such sputum would indicate that the coloration is not caused by blood, and further cultural tests in similar cases may reveal the presence of the *Bacillus prodigiosus*, human infection with which may not, after all, be extremely rare.

## The Restitutio ad Integrum After the Severe Affections of Childhood.

The question as to the amount of damage done by measles, scarlatina, and other infections of childhood to an individual's subsequent health, efficacy, and resistance to the diseases of maturity, and as to the amount of possible gain when applied against the loss, is an old and all-important one. It crops out in many directions. Scrofulous affections of childhood seem oftentimes to confer an immunity against tuberculosis in adult life. Those who are specially prone to severe infectious diseases in childhood seem to possess a certain immunity against cancer. At a recent medical meeting at Strassburg (*Deutsche medizinische Wochenschrift*, January 9) Czerny discussed an excellent way to trace a relationship between childhood infections and adult health, to wit, the status of those who are eligible to military duty. It has already been claimed that more breast than bottle-fed subjects are eligible. Czerny expresses the opinion that such a conclusion is unwarrantable, for bottle milk may replace perfectly breast milk under proper conditions. Further, any shortcomings from this source are quickly outlived. There are constitutional peculiarities, however, manifested in infancy, which can never be outgrown fully, and we find at the recruiting age evidences enough of the exudative diathesis. Among children typhoid carriers do not occur, for their bile is believed to be more bactericidal than that of the adult. It is a question whether recovery from myxedema, so far as the mental defect goes, is ever quite complete; or, perhaps, rather whether the intellect had been intact before that condition developed. It has been advocated in Germany that no recruit for the army be received who could not speak at the age of one year. Such a rule might keep out some defectives but it would exempt from military service many a sturdy and mentally sound citizen.

## News of the Week.

**Message on State Health.**—In a recent message to the New York State Legislature Governor Sulzer transmitted the preliminary report of the commission appointed by him to investigate public health matters in this State. The Governor in his message calls attention to the fact that there is now no well co-ordinated system of public health administration in the State and asks that the State Department be given broader powers. The chief recommendations of the committee may be briefly summarized as follows: That the tenure and compensation of the State Health Commissioner be such as to secure and retain the most efficient man in the State for that service, and that he be required to devote substantially his entire time to his official duties; that a public health council be established with power to adopt sanitary regulations; that the State Commissioner of Health exercise supervision over local health authorities and be specifically charged with the enforcement of the public health law; that the State outside of New York City be divided into at least twenty sanitary districts with an expert sanitary supervisor in each, devoting full time to health work; that the duties of town and village health boards, not otherwise provided for, be transferred to town boards and village boards of trustees; that health officers of towns and villages receive an annual minimum salary equivalent to at least 15 cents per inhabitant of the village or town; that health officers of towns and villages be charged with the following duties: (a) annual survey and continual supervision of their districts; (b) examination of all school children; (c) inspection of all school buildings and places of popular assemblage; (d) popular education as to public health; (e) securing full registration of communicable diseases and of births and deaths; (f) enforcement of public health laws and regulations; that modern statutes covering registration of births and other vital statistics be enacted; that authority be given to each city, county, village, and town to employ trained nurses as infant welfare nurses, school nurses, tuberculosis nurses, and to visit the sick; that the tuberculosis law be amended so as to provide (a) for more complete reporting of cases; (b) for supervision of reported cases by trained nurses; (c) for compulsory removal and detention of dangerous cases; that additional State provision for incipient cases of pulmonary tuberculosis be made; that a bureau of child hygiene and a bureau of public health nursing be added to the State Department of Health; that county hospitals for tuberculosis be established; that adequate laboratory facilities be made readily available for all health authorities; that contagious disease hospitals be established by local authorities, to be under the inspection of the State Department of Health; that midwifery be regulated by the State; that the reports of health officers be made presumptive evidence of facts stated, and such officers be freed from personal liability, if acting in good faith; that the educational work of the State Department of Health be extended; that encouragement be given to courses in sanitary science in educational institutions. The committee, which, as already stated, consists of Dr. Hermann M. Biggs, Mr. Homer Folks, Mr. John H. Kingsbury, Dr. E. R. Baldwin, Dr. W. E. Milbank, Miss M. A. Nutting, Mr. John C. Otis, and Mr. Ansley Wilcox, states that it will make further recommendations on the advisability of establishing a system of medical examination as a condition to securing a marriage license; the regulation of housing in second and third-class cities; the better protection of water supplies, and the establishment in medical colleges of a course of instruction in sanitary science which will ultimately be required of health officers.

**Dr. F. F. Friedmann,** who claims to have discovered a cure for tuberculosis, is said to have made application at Washington for a patent to cover the remedy and its manufacture. If the remedy is simply a culture of bacteria, it is difficult to understand how it can be patented. However, Dr. Friedmann is now in this country and the therapeutic value of his culture will soon be tested here, though he is reported to have refused to accept the terms of the widely advertised million-dollar test.

**German Hospital.**—The annual report of the German Hospital and Dispensary, New York, gives the total number of patients treated during the past year as 48,228, of whom 6,935 were in the hospital department, receiving 80,040 days of care, while in the dispensary department 106,849 consultations and treatments were given. At the annual meeting held last week, Mr. Adolph Kuttroff was elected president of the Hospital.

**Health Board Quits.**—The members of the Board of Health of Summit, N. J., have presented their resignations to the Mayor of the town, to take effect on March 1. The Board declares that the Common Council has refused to pay the bills which were approved and passed by the Board.

**Vivisection Bill Killed.**—The Judiciary Committee of the New York Senate on February 18, by a vote of six to four, refused to report the McClelland bill, creating a commission for the investigation and regulation of the practice of vivisection in the State. A motion to reconsider was laid on the table and it is probable that nothing more will be heard of this bill, at least until next year.

**Gorgas to Ecuador.**—The United States Senate on February 20 voted to grant permission to Col. W. C. Gorgas of the Isthmian Canal Commission to enter the service of the Republic of Ecuador for the purpose of cleaning up the port of Guayaquil, known as the "pest hole of the Pacific."

**Harvey Society.**—Prof. Edward G. Conklin of Princeton University will lecture before the Harvey Society at the New York Academy of Medicine on Saturday evening, March 8, at eight-thirty, his subject being, "The Size of Organisms and Their Constituent Parts in Relation to Longevity, Senescence, and Rejuvenescence."

**Pure Milk Bill.**—At the request, it is said, of Governor Sulzer, a bill was recently introduced in the New York State Legislature creating a Sanitary Milk Commission to take over certain duties of the Department of Agriculture and to be charged with the execution of all laws relating to the production, manufacture, storage, transportion, and sale of milk. The board is to be composed of a Milk Commissioner, at a salary of $7,000 a year, the Commissioner of Health of New York City, and the State Commissioner of Agriculture. The board will have the power to fix standards of purity for milk and to regulate its sale in every particular.

**Medical Licenses in Oregon.**—As a result of the recent examinations held by the Oregon State Board of Medical Examiners, licenses to practice

medicine in the State were issued to sixty-nine physicians, or seventy-two per cent. of those who applied.

**Medical Freemasons.**—A Lodge meeting of Medical Freemasons who are members of the XVIIth International Congress of Medicine will be held on Monday, August 11, 1913, in the Grand Temple at Freemasons' Hall, Great Queen Street, London W. C. The Most Worshipful the Pro Grand Master, the Right Hon. Lord Ampthill will open the Lodge at 5 P. M. and close it at 6 P. M., and at 4 P. M. a reception will be held in the Connaught Rooms, adjoining the Hall. It is requested that all who wish to be present will communicate with the Grand Secretary of their own jurisdiction as soon as possible in order that suitable arrangements may be made.

**Loving Cup for Dr. Deaver.**—Dr. John B. Deaver, patron of the John B. Deaver Surgical Society of the University of Pennsylvania, was the guest of honor at a recent meeting of the society and was presented by the members with a silver loving cup.

**Pennsylvania Alumni.**—At the twenty-first annual dinner and reunion of the Philadelphia Alumni Association of the Medical Department of the University of Pennsylvania, held on February 15, the following officers were elected for the ensuing year: *President,* Dr. Clarence P. Franklin; *Honorary Vice-President,* Dr. Howard E. Sutton; *Vice-Presidents,* Dr. Charles Smith, Dr. William Duffield Robinson, and Dr. Charles Claxton; *Corresponding Secretary,* Dr. B. Franklin Stahl; *Recording Secretary,* Dr. William S. Wray; *Treasurer,* Dr. Morris B. Miller. The sum of $500 was appropriated by the association for the establishment of a scholarship in honor of Dr. Roland G. Curtin and to be known by his name. This amount is to be increased by appropriations of $500 annually until the fund is completed.

**Sanitation of Cuba.**—The work of sanitation which has been carried on in the cities of Cuba has been widely reported and the excellent results acclaimed, but the interior of the island is still but little known, and it is, therefore, of interest to note what is being done in the mountains to the west of Santiago de Cuba where there are extensive copper mines. The health of the town of Cobre, a mining town of some two thousand inhabitants, is looked after by Dr. Guillermo de Piña, who is the Sanitary Commissioner of the District and the head of the hospital maintained at Cobre by the Cuba Copper Company for the care of its miners. During the past year Dr. de Piña treated 2,077 patients with only two deaths. In the hospital 1,870 patients were cared for, there being 54 cases of serious injuries and 514 of minor accidents in the mines. The record is the more remarkable as only a few years ago Cobre was the usual unsanitary Cuban village with not infrequent outbreaks of yellow fever, and this vast improvement is mainly due to Dr. de Piña's six years of faithful service.

**City Death Rate.**—During the week ending February 15, there were in New York City 1,732 deaths, a rate of 16.82 per thousand, as compared with 1,604 deaths and a rate of 16.17 during the corresponding week of last year. The increase was due largely to the greater number of deaths from pneumonia, from diseases of the kidney, and from violence. In measles, scarlet fever, typhoid fever, cerebrospinal meningitis, and pulmonary tuberculosis there were considerable decreases.

**Gifts to Charities.**—By the will of the late Mr. C. C. Weld of Newport, R. I., the Boston Lying-In Hospital receives $125,000, and the Boston Dispensary $100,000, while the residuary estate, valued at nearly $4,000,000, is in case the daughter of the decedent dies without issue, to be divided between the Massachusetts General Hospital and the Massachusetts Institute of Technology.

Mt. Sinai Hospital and the Montefiore Home, New York, receive $100 each under the will of the late Mr. Lewis Lowengood of this city.

The Methodist Hospital, Philadelphia, and St. Luke's Hospital, South Bethlehem, Penn., receive $21,000 each under the will of the late Mr. John Fritz of Bethlehem.

**New York Psychoanalytic Society.**—At the January meeting of the Society, the following were elected officers for the ensuing year: *President,* Dr. H. W. Frink; *Vice-President,* Dr. B. Onuf; *Secretary,* Dr. A. A. Brill.

**Fourth Councilor District (N. C.) Medical Society.**—At the annual meeting held at Rocky Mount on February 11, the following officers were elected: *President,* Dr. W. H. Smith, Goldsboro; *Vice-Presidents,* Dr. E. B. Quiller, Rocky Mount; Dr. G. D. Vick, Selma; *Secretary-Treasurer,* Dr. Henry B. Best, Wilson.

**Medical Society Elections.**—Marine County (Cal.) Medical Society: Annual meeting at San Rafael on January 16. Officers elected: *President,* Dr. H. O. Hund; *Vice-President,* Dr. W. J. Wickman; *Secretary-Treasurer,* Dr. A. H. Mays.

New Haven (Conn.) Medical Society: Annual meeting on January 15. Officers elected: *President,* Dr. William F. Verdi; *Vice-Presidents,* Dr. W. H. Crowe and Dr. Frank A. Kirby; *Secretary,* Dr. Charles E. Sanford; *Treasurer,* Thomas V. Hynes.

Perry County (Ill.) Medical Society: Annual meeting at Duquoin on January 14. Officers elected: *President,* Dr. Max Adles, Duquoin; *Vice-Presidents,* Dr. J. S. Templeton, Pinckneyville; Dr. J. S. Cleland, Swanwick, and Dr. H. W. Wolf, Tamaroa; *Secretary-Treasurer,* Dr. Rolla D. Pope, Duquoin.

Douglas County (Kan.) Medical Society: Annual meeting at Lawrence on January 14. Officers elected: *President,* Dr. S. T. Gillespie; *Vice-President,* Dr. E. Bumgardner; *Secretary,* Dr. H. L. Chambers; *Treasurer,* Dr. E. Smith.

Johnson County (Neb.) Medical Society: Annual meeting at Tecumseh on January 15. Officers elected: *President,* Dr. T. E. Fairall, Tecumseh; *Vice-President,* Dr. B. F. Gay, Tecumseh; *Secretary-Treasurer,* Dr. A. P. Fitzsimmons, Tecumseh.

Central Oklahoma Medical Society: Annual meeting at Enid on January 16. Officers elected: *President,* Dr. T. M. Aderhold, El Reno; *Vice-President,* Dr. D. D. McHenry, Oklahoma City, and Dr. W. E. Lamberton, Enid; *Secretary-Treasurer,* Dr. J. M. Cooper, Enid.

Franklin County (Penn.) Medical Society: Annual meeting at Scotland on January 21. Officers elected: *President,* Dr. William C. Schultz, Waynesboro; *Vice-Presidents,* Dr. Benjamin F. Myers, Chambersburg, and Dr. M. Webster Stoffer, New Franklin; *Secretary,* Dr. John J. Coffman, Scotland; *Assistant Secretary,* Dr. Paul P. Allen, Chambersburg, Penn.; *Treasurer,* Dr. Johnston McLanahan, Chambersburg.

Craighead County (Tenn.) Medical Society:

Annual meeting at Jonesboro on January 11. Officers elected: *President,* Dr. P. W. Lutterloh; *Vice-President,* Dr. Ira Ellis; *Secretary-Treasurer,* Dr. R. H. Willett.

Spokane County (Wash.) Medical Society: Annual meeting at Spokane on January 9. Officers elected: *President,* Dr. E. B. Nelson; *Vice-Presidents,* Dr. Charles F. Eikenbary and Dr. H. P. Marshall; *Secretary,* Dr. Carl H. Weisman; *Treasurer,* Dr. T. A. Vessy.

Milwaukee (Wis.) Medical Society: Annual meeting January 14. Officers elected: *President,* Dr. Gilbert E. Seaman; *Vice-President,* Dr. Hoyt E. Dearholt; *Secretary,* Dr. C. A. Baer; *Treasurer,* Dr. R. C. Brown.

Panhandle District (Tex.) Medical Society: Annual meeting at Wichita on January 15. Officers elected: *President,* Dr. J. C. Anderson, of Plainview; *First Vice-President,* Dr. Everett Jones, Wichita Falls; *Second Vice-President,* Dr. Ballew, Memphis; *Secretary,* Dr. J. J. Crume, Amarillo.

Yazoo County (Miss.) Medical Society: Annual meeting at Yazoo City on January 13. Officers elected: *President,* Dr. George Jones; *Vice-President,* Dr. W. E. Noblin; *Secretary-Treasurer,* Dr. S. W. Purifoy.

Portsmouth (N. H.) Medical Society: Annual meeting on February 4. Officers elected: *President,* Dr. J. D. Carty; *Secretary,* Dr. W. P. Crosby; *Treasurer,* Dr. C. W. Hannaford.

Aberdeen District (S. D.) Medical Society: Annual meeting at Aberdeen on January 29. Officers elected: *President,* Dr. Robert D. Alway, Aberdeen; *Vice-President,* Dr. James D. Jones, Groton; *Secretary,* Dr. W. D. Farrell, Aberdeen; *Treasurer,* Dr. J. E. Bruner, Frederick.

Lavaca County (Tex.) Medical Society: Annual meeting at Hallettsville on January 31. Officers elected: *President,* Dr. James E. Lay, Hallettsville; *Secretary-Treasurer,* Dr. Spiller, Yoakum.

**Obituary Notes.**—Dr. Kingman B. Page of New York, a graduate of the Bellevue Hospital Medical College in 1887, died at his home on February 19, aged 49 years. He was a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the American Urological Association, the Greater New York Medical Society, the Medico-Surgical Society, and the Harlem Medical Society, genito-urinary surgeon to St. Mark's Hospital Dispensary, and visiting genito-urinary surgeon to the People's Hospital.

Dr. William J. Callan of Brooklyn, N. Y., a graduate of the Long Island College Hospital in 1892, died at St. Joseph, N. Y., on February 13.

Dr. George H. Witter of Wellsville, N. Y., a graduate of the College of Physicians and Surgeons, Baltimore, in 1885, a member of the American Medical Association and of the New York State and Allegany County Medical Societies, and State Senator from the Fourth New York District from 1908 to 1910, died at his home on February 13, aged 54 years.

Dr. James Francis Duffy of Providence, R. I., a graduate of the University of Vermont College of Medicine, Burlington, in 1891, and a member of the Rhode Island State and Providence District Medical Societies, died at his home on February 8.

Mr. Joseph V. Stadish, for fifty years clerk of the Bellevue Hospital Medical College and of the University and Bellevue Hospital Medical College, New York, died on February 1 from angina pectoris. During his long service Mr. Stadish had endeared himself to thousands whom as medical students he had aided and encouraged, and at the time of his sudden death a plan was under way to present to him a testimonial commemorating his fifty years as clerk of the college.

Dr. James Jeremiah Williams of New York, a graduate of Bellevue Hospital Medical College, New York, in 1874, died at his home on February 12, aged 67 years.

Dr. James M. Gray of Hutchinson, Kan., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1883, and of the Kansas City Medical College in 1893, died at his home from pneumonia after a short illness on January 5, aged 50 years.

Dr. Francis H. Cohan of Leominster, Mass., a graduate of the Medical School of Maine, Portland, in 1901, a member of the American Medical Association and the Massachusetts State and Worcester County Medical Societies, and surgeon to the Leominster Hospital, died suddenly on February 13, aged 42 years.

Dr. Thomas Janes Carswell of Waycross, Ga., a graduate of the Medical Department of the University of the South, Sewanee, Tenn., in 1908, a member of the Georgia State and Ware County Medical Societies, and secretary of the Eleventh Councilor District, was injured in an automobile accident on February 10, and died a few hours later in the King's Daughters' Hospital, aged 35 years.

Dr. F. H. Aveline of Marion, Ind., died at his home on February 9, aged 55 years.

Dr. Edward H. Parker of Eau Claire, Wis., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1879, and a member of the American Medical Association and the Wisconsin State and Eau Claire County Medical Societies, died at his home suddenly on February 7, aged 58 years.

Dr. John S. Potts of San Francisco, Cal., a graduate of the American Medical College, St. Louis, in 1875, and of the College of Physicians and Surgeons, Keokuk, Ia., in 1877, and a member of the California State and San Francisco County Medical Societies, died at his home on February 9, from Bright's disease, aged 72 years.

Dr. Manuel Garcia Monteiro of Cambridge, Mass., a graduate of the College of Physicians and Surgeons, Boston, in 1890, died at his home from pneumonia, on February 14, aged 54 years.

Dr. Adolph O. Bjelland of Mankato, Minn., a graduate of the University of Minnesota College of Medicine and Surgery, in 1896, and a member of the American Medical Association and the Minnesota State and Blue Earth County Medical Societies, died recently at his home, aged 42 years.

Dr. James Reagles, Captain in the United States Army, retired, a graduate of the Bellevue Hospital Medical College, New York, in 1864, died recently at his home in Schenectady, N. Y.

Dr. Henry A. Savard of Lawrence, Mass., a graduate of Laval University, Medical Department, Quebec, in 1881, died at his home after a long illness, on February 12, aged 50 years.

Dr. Samuel Souders of Dean, O., a graduate of the Bellevue Hospital Medical College, New York, in 1871, and a member of the Ohio State and Montgomery County Medical Societies, died at his home on February 9, aged 81 years.

# Correspondence.

## ERYSIPELAS COMPLICATING MEASLES.

To the Editor of the Medical Record:

Sir:—About five weeks ago I was called to attend E. K., five years old, for what proved to be measles. This also developed in two other children of the family, and was, according to the account of the parents, a second attack with all the three children. When the rash was beginning to fade and the temperature had gone down to 101° or so, the child suddenly developed a temperature of 104°, and at the same time a red swelling appeared over the right eye. This swelling afterward ran the typical, though mild, course of a case of erysipelas involving only the right side of the face, and terminating in about eight days without any recurrence. As I have never seen erysipelas as a complication of measles, and as I have not seen it mentioned in any of the books as a complication in this disease, I have thought it worth while to report this case.

J. C. Josephson, M.D.

1393 Washington Ave., New York.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

SANATORIUM TREATMENT—RARE BONE DISEASE—WASHING RENAL PELVIS WITH COLLARGOL—INSURANCE VOTE IN PARLIAMENT AND CHEAP DRUGS—ST. THOMAS'S HOSPITAL NEW DEPARTMENT—ITEMS—OBITUARY.

London, February 7, 1913.

Questions as to the value of the sanatorium treatment are continually cropping up in conversation and many more doubts are expressed than appear in formal articles. Sometimes these doubts find expression at the societies. Thus at the Royal Society of Medicine last week Dr. H. D. McCullock expressed a doubt whether our British sanatoriums might not be a waste of money on account of the absence of high altitudes and, further, whether *x*-rays offered really satsfactory evidence. Dr. Fred Taylor, president of the section, held that a comparison of modern sanatorium treatment with former methods either in hospital or at home would be of considerable value.

The paper which elicited these remarks was by Dr. Noel Bardswell, and comprised the records of 1079 patients discharged from King Edward Sanatorium from July, 1907, to July, 1911. The diagnosis of pulmonary consumption was confirmed by the staff in 1027 cases. Of these bacilli were found in 82.7 per cent. One hundred and twelve had been lost sight of, but 915 were traced to October, 1912. Of these 915, bacilli had been present on admission in 764, but in 151 none was detected at any time. Four hundred and thirty-seven of the 764 were alive and well in 1912, and 327 were dead. As to the disappearance of bacilli while under treatment, of the 764 admitted with bacilli present, 148, or 19.3 per cent., lost them before discharge; of these 148 in 1912, 124 were well or alive and 24 dead. In commenting on the records Dr. P. Horton-Smith Hartley emphasized the importance of distinguishing in pulmonary consumption cases with tubercle bacilli in the sputum from those without. As to diagnosis in the latter he said a focal reaction after an injection of tuberculin left little doubt. Dr. T. D. Acland was not satisfied bacilli in the sputum afforded a fair test of their presence in the lung and asked about the relationship between bacterial tests and the presence of bacilli. Dr. Cecil Wall suggested some additional data, such as age of patients, time passed in sanatorium and duration of disease would add to the value of the statistics. Dr. F. Parkes Weber agreed that the only criterion on which to base a diagnosis was the presence of bacilli in the sputum. Many persons had a certain amount of tuberculosis but never became tuberculous patients. They reacted to modern bacterial tests. Examination by the old physical signs aided by Roentgen rays should be employed in addition to other methods.

At St. Bartholomew's Hospital the Hunterian Society held a clinical and pathological meeting on Jan. 22, when an interesting exhibition of cases, specimens and skiagrams was on view. Among the cases the following cannot fail to interest you: It seems almost if not quite unique and Mr. P. Kidd, who showed it, said he had searched the literature in vain for a parallel case. The patient was a boy of eight who from his third year had been from time to time fracturing his long bones. At three years of age he fractured the right femur and the thigh swelled to such an extent that amputation had been advised under the impression that it was a case of sarcoma. The parents did not consent and the swelling subsided. At six, he broke his left arm and similar swelling followed and subsided. Two months ago he again injured this arm and it swelled again. The boy's mother and eldest brother had both had multiple fractures and lost a limb from sarcoma. The mother's father and brother had fractured bones from the slightest injury. The patient was a pale lad; his skull, face, spine, ribs, sternum, clavicles, scapulæ, and pelvis seemed normal. His left arm showed a fusiform swelling 15 inches in circumference, with tense, shiny skin, and superficial veins dilated; movements of elbow and shoulder joints free. A skiagram showed a fracture of the shaft and a mass of irregular, trabeculated new bone, but most of the swelling threw no bony shadow. Swelling of the right femur extended throughout the length of the bone, the entire shaft being seen in the skiagram as a meshwork of trabeculæ; a similar meshwork was seen at the upper end of the right radius, of the left tibia and the tarsal bones. The right and left tibia and fibula, and radius and ulna were all bent about their middles. Mr. Kidd hardly knew what name to give the disease. There were no signs of rickets or syphilis. The skiagrams suggested fibrocystic disease of bone (von Recklinghausen), but he thought every obscure bone disease was labeled as his. In osteomalacia the bones bent, but these broke. On the whole he was inclined to ticket it as an irregular type of that somewhat indefinite class *osteogenesis imperfecta*.

At the same meeting Mr. Kidd also showed skiagrams of kidneys of which the pelves had been filled with collargol. He is sure such injection is a valuable addition to our methods of examining renal cases. It is not difficult to do and scarcely, if at all, dangerous—in fact, he habitually washes out kidneys with collargol with the ureteric catheter in his out-patient department. There is one drawback, the patient cannot be anesthetized as it is quite impossible to tell how full the renal pelvis may be unless he is conscious to signify when pain appears. The radiographer, however, finds it best for these

patients not to be rendered unconscious. As to the two specimens, in one he had been able to prove by this method that one kidney was absent—in the other intermittent blocking of ureter resulting in widely dilated renal pelvis.

A supplementary vote is to be asked for during the next few days for nearly two millions, the amount by which Mr. Lloyd-George underestimated the initial cost of the act. Questions in parliament have been many all the week with a view of eliciting information and raising debate, but with little success. Members have been told that the sum set apart for drugs and appliances is so inadequate that some wholesale houses have been tempted to reduce quality and that "insurance quality" is now a recognized trade term. The size of bandages has been reduced so much that the Marquis of Tullibanding said he had some which might do to bind up a hen's leg but certainly not a child's. Another member said he had received a newspaper advertising "washed bandages" and drugs "suitable for chemists on the insurance panels."

The new department at St. Thomas's Hospital for tuberculosis was opened on Monday. It is very complete and forms an independent unit which fits in with the scheme of the Borough of Lambeth controlled by the M. O. H. It occupies the ground floor of the southern block of the hospital and contains a large waiting hall in connection with social workers' room under the lady almoner's department which makes inquiries as to the position of patients, the condition of their homes and advises them as to their mode of living and assists them otherwise. Beside the physicians' room is a small one for microscopical examinations of sputum and a dark room. Bacteriological work will be carried out in the hospital laboratory where the tuberculosis officer (Dr. Wingfield) will have the assistance of its staff. Tuberculosis patients under treatment by the medical staff were transferred to the new department on Monday and new ones will be admitted there in future. A small ward has been set apart for observation of special cases in the hospital.

Sir Launcelotte Gubbins, Director General of the Army Medical Service, and Sir Berkeley George Moynihan, were made Honorary Fellows of the Royal College of Surgeons in Ireland at the annual meeting on Feb. 1.

At a meeting of the profession in Edinburgh held on the 29th ult. in the Royal College of Physicians it was decided to found a memorial of the late Dr. George Gibson, whose death I mentioned in my letter a fortnight ago. It is proposed that the form shall be a research scholarship in clinical medicine, which is certainly appropriate to one devoted to that subject.

The Right Hon. Lord Ilkeston, M. D., F. R. C. P., died on Jan. 31 in his seventy-third year. He was better known to the profession as Dr. Balthazar Foster, physician to the General Hospital, Birmingham, and professor of medicine Queen's College. He was a member of the General Medical Council from 1887 to 1897. His treatise on "Method and Medicine" appeared in 1870 and was followed in 1874 by his perhaps better known "Clinical Medicine." Later he took up politics, especially in relation to the profession, with great earnestness, wrote on the public aspects of medicine and the "Powerlessness of the Profession" and eventually became a candidate for parliament, to which he was elected in 1887. He was then knighted and made P. C. He retired in 1910 and was raised to the peerage as Baron Ilkeston. He had been secretary to the Local Government Board, 1892-5, where he worked in favor of sanitary progress. Among other honors conferred upon him were D. C. L. of Durham and LL.D. of Montreal. He is succeeded in the Barony by his son, Balthazar Stephen S. Foster, born in 1867. Many societies, both medical and political, were represented at the funeral, Feb. 3.

Dr. Ch. Orton, consulting physician to the North Staffordshire Infirmary, which he had served in the several offices on the active staff from 1862 until 1889, died on Jan. 16 at the age of seventy-three. He at one time was in the army and attained the rank of Surgeon Major. He went to the Franco-Prussian war and wrote an account of his visit jointly with Dr. Spanton.

Dr. J. F. J. Sykes, Medical Officer of Health for St. Pancras for the last twenty-three years, has died in his sixtieth year. He was awarded the Haward medal of the Royal Statistical Society in 1900. For some years he was an examiner in hygiene in the Science and Art Department.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

THE PLAGUE—PREVENTIVE VALUE OF DISINFECTION—MANILA MEDICAL SOCIETY—PERNICIOUS MALARIAL FEVER—STUDY OF MALARIA IN MINDORO—APPARENT INCREASE OF TYPHOID FEVER.

MANILA, P. I., January 18, 1913

THE last case of plague in the Philippine Islands occurred in Manila on December 25, 1912. Since the beginning of the outbreak, last June, there have been fifty-nine cases, of which fifty-three died.

During the month of December, in connection with the plague suppressive measures, a very interesting experiment was carried out. On December 17, 1912, a case of human plague occurred at No. 4 Calle Baraca. As soon as the case was removed, and before disinfection, two guinea-pigs, free from fleas, were placed in a wire cage and the cage then placed upon the floor near the place where the patient had slept. On December 21 both guinea-pigs died of typical plague, the diagnosis being bacteriologically confirmed. A similar experiment was carried out in a house on Calle Cabildo, and one on Calle San Fernando, where cases of plague had occurred, but in which immediate disinfection had taken place. In neither of these places did the guinea-pigs contract plague. This experiment would seem to indicate that the disinfecting and insecticide measures which are carried out by the Bureau of Health are effective.

The monthly meeting of the Manila Medical Society took place in the amphitheater of the College of Physicians and Surgeons, on January 6, 1913, at 8:30 P.M. Major Ashburn, the chairman of the Army Board for the Study of Tropical Diseases as they exist in the Philippine Islands, presented some additional evidence which tended to show that there were two distinct viruses concerned in the infection of smallpox.

Following this paper the following officers were elected for the ensuing year: President, Major Percy M. Ashburn; vice-president, Dr. R. E. L. Newberne; editor of the Bulletin of the Manila Medical Society, Dr. W. E. Musgrave; business manager of the Bulletin, and treasurer of the So-

ciety, Dr. W. E. Woodbury; associate editor of the Bulletin, Dr. A. G. Sison. Dr. Almon P. Goff was elected councillor for five years.

During the past week two deaths from pernicious malarial fever occurred among children in the city of Manila. These cases were microscopically confirmed and, as the children had not been out of Manila at any time, it appears that the infection must have been contracted in the city. So far as known, these are the first authentic cases of malaria that could be reasonably ascribed as having been contracted in Manila.

On January 12, 1913, a party composed of members of the Bureau of Health, the College of Medicine and Surgery, and the Philippine General Hospital proceeded to the Island of Mindoro, to the San José estate for the purpose of making a thorough clinical study of the cases of malarial fever that have been occurring in such numbers among the employees of the sugar companies that have recently begun operations on that island. Far back in the Spanish history of the island Mindoro has been considered one of the homes of pernicious malarial fever, and deaths frequently occurred among those who ventured there. Mindoro is one of the largest and most fertile islands in the Philippines, and yet is only sparsely inhabited, and this lack of population is probably due in a large measure to the pernicious malarial fever which has prevailed there in the past.

Typhoid fever is beginning to be a larger and larger factor in the public health situation in the Philippine Islands. It is difficult to obtain a reliable expression of opinion as to whether the disease is actually on the increase, or whether it has been overlooked heretofore. On account of the fact that the time of the health officials in the past has been so much absorbed by diseases like cholera, plague, smallpox, and leprosy, and since these have now been brought under control, it would seem possible that perhaps diseases like typhoid are receiving more attention. A few years ago the disease seemed to prevail more frequently in the vicinity of army posts and it is possible that it may have spread from there. Typhoid prevails now mostly in the western coast section of the mountain province, Pangasinan, and Pampanga Provinces. The exact manner of its spread would be a matter of much interest. There are no public water supplies and the use of other than sterilized canned milk is almost negligible.

1. **Ear Complications of Infectious Diseases.**—C. R. Borden has collected a series of 2,232 cases of scarlet fever, measles, and diphtheria. Of this number, 746 cases of scarlet fever showed 11 per cent. of aural complications: 456 cases of measles, 28 per cent., and 952 cases of diphtheria, 2.9 per cent. Sixty-eight cases of mixed infection were the highest in the percentage of all middle ear complications, viz., 44 per cent. In measles, middle ear and mastoid symptoms occur during the height of the active process and adults are particularly liable to mastoiditis. In scarlet fever, middle ear involvement comes at any time during the course of the disease, and is by no means limited to the active stage. Adults are not especially liable to mastoiditis in scarlet fever. In diphtheria, otitis media or mastoiditis are not as active as in scarlet fever or measles, and the diagnosis is far more difficult to make for this reason.

3. **Mouth Breathing Following Adenoidectomies.**—I. Sobotky emphasizes the following points: For the cure of persistent mouth breathing nasal breathing exercises have not proven efficient. An operative treatment of the nasal condition is indicated. Such treatment must be appropriate for the age of the patient. Patients should have their adenoids removed before the typical high palatal arch is formed. If the high arch is formed the treatment should be dental, such as spreading the arch and regulating the teeth. Cutting a slice of mucous membrane from the enlarged lower turbinates, as an aid to nasal respiration, has given good results. A submucous resection should not be done in children under sixteen. Electrolysis, using the bipolar method, is effective in reducing the enlarged turbinates but is not suited for children.

10. **Peritoneal Sacculation of the Ovaries.**—E. Reynolds reports three cases of this condition. The history of the first case was as follows: A neurasthenic and somewhat ill developed girl of 22 years complained of sharp pain, varied by acute exacerbations, in the lower abdomen and back, mostly right-sided. This pain was of about a year's duration and the acute attacks were accompanied by frontal and occipital headaches, with hot flushes, and sweating of the right arm only. During these attacks she was somewhat hysterical. On examination there was a small uterus in retroversion, with some tenderness over the right broad ligament, but nothing else abnormal was felt. After two months' observation, and failure to obtain relief by minor means, the pain was plainly becoming more severe, and operation was advised. On January 15, 1911, the abdomen was opened by a small exploratory incision and the movable fundus drawn up. The left ovary was at once seen to be moderately enlarged and cystic, but in normal peritoneal relations. The right tube was visible throughout the greater part of its length, but at its distal extremity appeared to fuse with the broad ligament. On more careful inspection it proved to disappear into a slit in the broad ligament about three-quarters of an inch long and with edges so sharply defined as to be clearly congenital. Upon traction on the tube the ovary was visible lying within a peritoneal pocket, the mouth of which was too small to permit its withdrawal. The utero-ovarian ligament was perceptible at the inner angle of the slit. This was seized with forceps, and after some manipulation it proved possible to so rotate the ovary within the pocket as to bring it to the opening by one pole, in which position it was possible to withdraw it. It was moderately enlarged by several small follicular cysts and two good-sized corpora lutea. After resection of both ovaries, closure of the sacculus, a suspension of the uterus and the removal of the appendix the abdomen was closed. The patient made a good recovery and the attacks of ovarian pain ceased.

11. Carcinoma of the Lung. M. Freiman.

1. **Asellius and the Lymphatic Circulation.**—F. P. Henry notes that Asellius discovered the chyliferous vessels in 1622, in the course of an experiment in which he was trying to demonstrate the movements of the diaphragm in a dog. The lacteals were demonstrated in man in 1628, the subject being a criminal who was examined one and a half hours after his execution. The next important step in the history of the lymphatic circulation was the discovery of the thoracic duct by Pecquet, of Dieppe, in 1647. The honor of discovering the lymphatic vessels belongs to Rudbeck, of Sweden.

2. **Friedmann's Tuberculosis "Remedy."**—C. T. J. Achard states that while Friedmann has admitted under pressure that the living tubercle bacilli composing his "remedy" are obtained from the turtle, nevertheless he still refuses to describe the method he employs. In his informal report he describes at length his clinical results in a great variety of tuberculous cases treated with his remedy, by intramuscular and intravenous injection, sometimes one or the other, sometimes both simultaneously. He asserts that patients show surprising improvement after one or two injections. He injects his bacterin into newborn infants, although it contains living tubercle bacilli, and says that somewhat over one year after this inoculation not the slightest trace of scrofula or tuberculosis is to be found in any of these children. Friedmann's clinical results have been confirmed by a number of clinicians, although Blaschko and also Heymann showed only indifferent results in cases of skin tuberculosis and lupus. Citron admits that for treatment and for prophylaxis the use of living germs is correct in principle and was adopted by Jenner and Pasteur, but he insists that great care must be exercised as long as the details of Friedmann's method are not known; he refers to Pasteur's experience with chicken cholera vaccine, in which the avirulent virus became virulent and caused destructive epidemics.

5. **Scoliosis and School Seating.**—J. W. Sever concludes from his study that all school chairs and desks should be adjustable to height. Chairs and desks adjustable in other directions are not necessary. A slight plus distance of about one inch is a good standard to go by in the relation of the desk to the chair seat. The desk top should slope twelve to fifteen degrees, and should be wide enough to allow the whole arm to rest on it in writing. The chair seat should be flat with rounded corners and edges; or slightly concave to fit the buttocks. The chair back should be wide with but two outside uprights; no higher than the lower part of the shoulder blades, with an adjustable crossbar, convex forward and concave from side to side, to fit the lumbar curve. From a sanitary point of view, single standard desks and chairs are good, provided the other qualifications are not lacking. Benches, chairs of the kitchen backed type, movable chairs and settee chairs are distinctly bad. Physical education departments are essential in connection with all school departments. Pupils should have frequent rest and exercise periods.

6. **Routine Disinfection of Schools.**—J. T. A. Walker notes that the presence of a certain proportion of infectious children in schools is admittedly unavoidable. These children diffuse a certain amount of infective material, the removal of which by means of frequent and thorough washing of classrooms and cloakrooms is, on the ground of expense, impossible, or is at least so regarded by the education authorities; the daily sprinkling of the floors with a disinfectant solution offers an inexpensive and easy method of minimizing the harmful effects of that material during the intervals between cleansing. Viewed in this light—not as a panacea or as a substitute for cleansing—it is difficult to understand why the benefits to be derived from this process should not appeal more generally to those responsible for the management of the public schools.

10. **The Worsted Truss.**—W. B. Jennings states that there is nothing new in the use of worsted as a truss for infants, but it seems that many of the younger generation in medicine are not familiar with this use. The directions for the construction of the truss are as follows: Take eight or ten strands of a skein of white Germantown knitting wool, make a loop, and place the skein around the child's body below the navel, tighten, and bring the knot over the external ring, cut the free end, and bring it down on the inside of the thigh near the perineum and back up over the gluteal fold; then tie the cut free end to the band of worsted already around the pelvis. The author does not wish to be misunderstood in regard to the radical cure of hernia, but he strongly recommends the worsted truss for the newborn and infants a few weeks or months old, to be used until the hernia is cured (the muscles having become stronger) or until such a time as the child is old enough to stand the shock of an operation. It is simple, effective, and easy for the mother to learn to put on. It does not irritate or chafe, is easily washed, and is not expensive.

3. **Benzol in Leucemia.**—F. Billings reports five cases of leucemia in which he employed this remedy. He refers to the fact that this method of treatment was introduced by von Koranyi. The doses administered by the author were 7 minims, gradually increased to 15 minims, four times a day, shortly after meals and at bedtime. He concludes that benzol in the doses given may at first stimulate the bone marrow, but very soon the effect is to make the leucocytic marrow hypoplastic. This may seem paradoxical, but it is apparent clinically. One is impressed with the drug as a powerful agent—a two-edged sword, which is apparently a remedy of great promise in leucemia, but which used carelessly may defeat the purpose of its use and produce an equally serious condition, namely, a plastic grave anemia, hypoplastic bone marrow and a fatal termination. The author advises the cautious use of only pure benzol. One should carefully watch its effects by frequent examination of the patient and his blood.

7. **Medical Supervision of Factories.**—W. I. Clark, concludes that it is possible for a simply equipped medical department to control with success the sickness and disability from accident in a large factory. A complete physical examination of all employees is perfectly possible and of great advantage to employer and employee. A system of prophylactic treatment in cases of sickness and accident will materially lessen the amount of sickness and decrease the loss of time. The sanitation of a large fac-

tory and all matters pertaining to the general health of the employees can best be maintained by a medical department. Far from exciting distrust and antagonism, a shop hospital creates a feeling of good will between employee and his employer.

**8. Technique of Gastroenterostomy.**—W. Bartlett describes the method employed by him for some years in performing gastroenterostomy, which allows the position and direction of the incision in both stomach and bowel to be accurately located better than the ordinary operation. After the abdomen has been opened the author exposes the highest part of the jejunum, without altering its normal direction, as it passes out from under the peritoneum. Two guide sutures are then placed in the wall of this structure at two points high up and almost 7 centimeters apart. The stomach is then brought down through an opening in the transverse mesocolon and the posterior wall of this viscus is matched accurately to that portion of the jejunum between the sutures. With the higher suture the contiguous stomach wall is caught at a point about midway between the two curvatures, while the lower, in a normal case, is inserted into the stomach wall, well toward the right and at, or very near, the greater curvature. Thus the position and direction of the jejunum determine the intended incision in the stomach so that when the viscera are replaced in the abdomen at the completion of the operation, they lie in approximately their normal positions. A continuous Lembert suture of silk is then placed, uniting the two points at which the viscera have been approximated by the guide sutures. The author's gastroenterostomy clamp is now placed in position with the middle blade under the line of union made by the running suture. The clamp is then locked, and the stomach and intestine are opened. An inside row of through-and-through continuous sutures is carried completely around the opening. The clamp is now removed, so as to facilitate approximation and the through-and-through continuous sutures are covered by an outer row of silk sutures, which brings together the serous surfaces. The lips of the wound in the transverse mesocolon are now attached to the suture line in several places. The gastroenterostomy clamp is made up of three blades held together by two screws. The advantages of using the clamp are two-fold; it exerts a uniform pressure along its three blades, and this pressure can be graduated to any desired degree, since two of its blades float.

**9. Grafting of Cancer.**—W. J. Mayo notes that cancer grafting may occur spontaneously, especially at points of contact like the labia, and in the gastrointestinal tract. In the large intestine, at least, grafting may occur not only by direct contact, but by the detachment of cancerous cells and their carriage to distant points. These possibilities have been recognized since the days of Rokitansky and Virchow, but little has been written about them in recent years. Admitting the possibility of spontaneous grafting, one must also recognize that it may occur from surgical manipulations, and the author gives illustrations of where it is liable to occur. Since one of his early experiences he has practiced searing the raw surfaces of the stomach and duodenal stumps following partial gastrectomy for cancer, because he believes grafting may happen from the bits of loosened cancer tissue freed at the operation and left in the stomach cavity. Cancer occurs frequently and is especially common in Douglas' pouch, and the ovaries are specially susceptible and the original focus may be obscured. Such pathological accidents may occur in skin grafting as epithelial cancer has a potential initiative far in advance of normal epithelium. One cause of the small percentage of cures of cancer of the cervix is the proximity of the ureters to the cancerous growth. While they are not often involved primarily, one cannot push them away from their contact with the cancerous growth without risk of infection. Traumatic dissemination of cancer growth is not rare, and may occur through ignorant handling of the cancer tumor. Embolic vascular dissemination is also common, especially in cancer of the rectum, the infected thrombi being carried through the derivatives of the portal vein to the liver. For nearly fifteen years the author has abandoned cutting instruments and has used the cautery in performing vaginal hysterectomy for cervical cancer, and has had with it a better percentage of cures. The better results of abdominal hysterectomy for cancer of the cervix may not be due so much to the pelvic and iliac lymphatics as to the thorough cauterization of the cervix very probably before opening the abdomen. The removal of pieces of tumor for microscopic examination should be done with some precaution and, if possible, preparations should be made for the immediate removal of the growth if malignancy is detected. In any operative work on cancers a specialized technique should be used, considering them as foci of virulent infection. The first and most important thing in these operations is wide local dissection, and Heidenhain's rule of cutting at least three centimeters away from the visible disease is now considered too narrow for safety. The second principle is the removal of the tributary lymphatics, and the third is to avoid traumatic dissemination of malignant cells during the operation and preventing the possibility of postoperative grafting by proper prophylaxis.

7. Congenital Absence of Both Thumbs. J. H. Sequira.
8. A Case of Acute Intestinal Obstruction Following Cesarean Section. J. B. Banister.

**1. Etiology of Endemic Goiter.**—R. McCarrison states that the changes which take place in the thyroid gland as the result of goitrous influences at first stimulate the organ to increased activity, but the increased activity so induced is early followed by damage to the secretory epithelium and by degenerative changes which impair its functional activity. There is no evidence of the existence in the thyroid gland of goitrous individuals of any specific *contagium vivum*—whether microscopic or ultramicroscopic—to which the malady can be attributed. Acting on the assumption that the intestinal tract might be the seat of infection, the author tried the effect of intestinal antiseptics in the treatment of this disease. Of 82 cases treated with thymol 68 were cured. When thymol is prescribed in such large dose as 10 grains twice daily the patient's dietary should contain no solvents of the drug. This should be administered in the form of a coarse powder washed down by a draught of water. Of 8 cases treated with soured milk, 4 were cured and 2 were improved. Vaccines prepared from organisms contained in the feces of sufferers from goiter were employed in the treatment of certain cases, in every one of which a complete disappearance of the thyroid swelling took place provided there were no degenerative changes in the gland. Equally striking results were obtained with a staphylococcus vaccine. The successful vaccine treatment of goiter is further confirmation of the view enunciated by the author that goiter is due to the presence of a living organism of disease in the intestinal tract. A conspicuous feature of this treatment and one which brings it into line

with the treatment by iodine, intestinal antiseptics, and the *Bacillus bulgaricus,* is the fact that the patients lose flesh and the skin becomes of a healthier tint.

2. **Tumors of the Kidney.**—R. H. J. Swan notes that the symptoms of a renal growth vary to a certain extent with the nature of the tumor present. The three prominent symptoms of hypernephroma are hematuria, pain, and the presence of a renal tumor. Hypernephroma is most common between the ages of 50 and 70 and is of comparatively slow growth; sarcoma is more common in childhood and forms a rapidly growing tumor with early cachexia. Carcinoma is a disease of later life, gives rise to more pain, and usually to constant hematuria; whereas in sarcoma hematuria may be absent, and in hypernephroma is usually of an intermittent type. Glandular enlargement is more common in carcinoma, either about the kidney or in distant glands, whereas a pulmonary or osseous deposit is more usual with hypernephroma. Carcinoma and sarcoma tend to infiltrate the surrounding tissues more rapidly than hypernephroma, so that the resulting tumor of the kidney may be more fixed in position.

3. **Bone Marrow Metastases in Gastric Cancer.**—A. W. Harrington and A. M. Kennedy report a case of this condition in which the blood bore a close resemblance to that of pernicious anemia. A study of the blood in the few cases which have been fully investigated shows a strong myeloid reaction, numerous erythroblasts and myelocytes being found. Most of the cases in which carcinoma simulated pernicious anemia closely were probably cases of metastases in the bone marrow. In the diagnosis of the latter most reliance is to be placed on the bone pains and the condition of the blood. In both of the authors' cases the bone pains were very severe and the tenderness was marked. With regard to the blood the points to be laid stress on are the high color index, megalocytosis, and the presence of erythroblasts and myelocytes in considerable numbers. Leucocytosis is common, but seems to be variable. In any case of grave anemia the presence of pains and tenderness of the bones should always arouse suspicion of carcinoma of the bone marrow.

1. **Vaccines and Fever.**—E. C. Hort performed a series of investigations to determine the essential cause of the fever of infective disease. The keystone in problems of immunity is the antigen, or substance that provokes the manifestation of antibodies; while in the pathological problems presented by fever, inquiry must always start from the pyrogen or substance that provokes the manifestation of fever. Both sets of problems are closely bound up with the subject of the pyrogenetic action of vaccines. The experimental basis of the theory that dead bacterial protoplasm is the direct source of the fever of infective disease is the undoubted fact that fever does frequently follow the injection into healthy subjects of dead cultures of certain organisms. At first sight this evidence would seem to be conclusive, especially if fever were found to follow the injection of all known forms of dead pathogenic bacteria and protozoa. It has, however, for some years been recognized that there are exceptions to what is by many still believed to be a general rule. For example, injection of dead cultures of the bacillus of Koch, *B. anthracis* and *B. diphtheriæ* into healthy subjects has from time to time been found not to be followed by fever. The author's observations appear to show that organisms recovered from tissues other than the blood, and injected at once, possess no pyrogen, but that when grown on laboratory media they readily elaborate a contaminating pyrogen from such medium, which they subsequently absorb. The author's observations also show that the concentration of body pyrogen cannot be high in the infected organs, since the tissue material injected in some of the cases was considerable in amount. Owing to the difficulty, however, of freeing organisms recovered in this way from tissue débris, their enumeration cannot be satisfactorily carried out. Moreover, it is conceivable that absence of pyrogen in the dead organisms after recovery from the body might be explained by exhaustion of any pyrogen they might have contained while in the body during the continuance of fever. The low concentration of pyrogen, however, already demonstrated in the blood plasma during high fever, and the fact that injection of organisms recovered from the body at an earlier stage of infection shows them also to be pyrogen free, make such a view improbable.

2. **Apyrexial Typhoid.**—N. Flower reports the case of a woman aged 60, who had resided in the same house for more than thirty years, and during that period had never required medical assistance for more than minor ailments. A careful investigation into her previous history precluded all possibility of any previous attack of typhoid fever. The present illness commenced in the first few days of September, with the usual feelings of malaise, and with gradually increasing diarrhea. She took to her bed on September 8th. When first seen, on September 10th, the patient was in an exhausted condition, with a dry, furred tongue and subnormal temperature. The outstanding feature of the case at the time was the exceedingly profuse diarrhea, which persisted in spite of all the usual remedies. Two days later the patient began to wander, and sank into a semi-comatose state, in which she remained for the ensuing fourteen days. During this period the intestinal symptoms were unchanged, there was a moderate distention of the abdomen, but no spots or enlarged spleen were present then or later. The Widal reaction on September 16th was positive in every dilution. From the onset of the attack until September 25th (that is, the fourth week of the disease), when complete consciousness returned, the mouth and surface temperatures were invariably subnormal, and the rectal temperature, taken twice daily, never exceeded 99.4°. From September 26th to October 4th the mouth and rectal temperatures each reached their maximum of 99.6° and 100.4° respectively, after which they dropped again. During the fourth week a further specimen of serum was obtained for the purpose of comparative agglutination reactions to *B. typhosus* and other allied organisms, with the following results: *B. typhosus* agglutinated up to 1 in 2,000. *B. paratyphasus B.* agglutinated up to 1 in 200. *B. paratyphosus A.* agglutinated very slightly. *B. enteritidis* (Gaertner) agglutinated not at all. The patient ultimately made a good recovery.

4. **Adrenalin in the Treatment of Non-Corrosive Poisoning.**—J. L. Jona states that if, after the introduction into the stomach of a poisonous chemical substance whose general toxic action depends partly upon the rate at which it enters the circulation, one is able to limit the rate of absorption of the drug—for example, by diminishing the blood supply to the mucosa of the stomach—time is provided for the preparation and adoption of methods to neutralize any possible action which would normally follow the introduction of the particular substance into the stomach, either by removing it altogether by means of a stomach tube and a stomach washout, or by inactivating it by means of a chemical antidote. Particu-

larly valuable would such an agent be which would lower the rate of absorption into the circulation of a substance which, entering the blood in large quantity, would destroy the life of the individual, but which the body is able, by the exercise of special powers to efficiently neutralize when it gains entry into the economy slowly. To such a category belong the cyanides. Theis and Buttron have demonstrated that when an animal has been filled by a lethal dose of KCN the amount of cyanide present in the organs diminishes on standing while Lang and Grober have shown that when HCN is introduced into the diet of an animal the amount of cyanide in the stomach diminishes, while the amount of sulphocyanate in the saliva and urine is increased. The intraperitoneal injection of adrenalin has been found by Exner to diminish the rate of absorption of a poison, such as strychnine or potassium cyanide, when introduced into the stomach. This academical piece of work suggested the investigation of the effect of the introduction of adrenalin into the stomach on the absorption of rapidly-acting poisons, such as cyanides, strychnine, and aconite, also introduced into the stomach, and whether such administration of adrenalin had any value in the practical treatment of accidental poisoning by these rapidly acting drugs. From the author's experiments on rabbits and dogs it is concluded that in the extract of the medulla of the suprarenal gland, one has an agent which will convert the stomach or other absorbing viscus on which it is acting into a practically non-absorbing bag in which the poison lies, ready to be absorbed when the action of the adrenalin passes off, but at the same time being absorbed in relatively small amount while the adrenalin is acting; and so a respite is gained during which the poison can be removed by mechanical means or neutralized *in situ* by some chemical antidote.

---

## Berliner klinische Wochenschrift.

*January 27 and February 3, 1913.*

**Treatment of Eclampsia.**—Veit endeavors to cover this subject very briefly. He is quite convinced that the toxin of eclampsia comes from the albumin of the periphery of the placenta, and predicts that this view will soon be universally accepted. Abderhalden's optical serodiagnosis of pregnancy seems to have turned the scale in placing the source of the toxin. The phenomenon is in no wise due to the entrance of villi into the blood stream which is known to occur in special cases. The human female is the only one who suffers from puerperal eclampsia, and the penetration of the villi is not without significance in eclampsia, for this phenomenon does not occur in animals until we descend very low in the scale of organization—to the leech, for example, in which the villi also enter the maternal placenta. When foreign and toxic albumin enters the blood a counter poison must form, but as yet nothing is known of it, nor under what conditions it fails to form. We cannot, therefore, prevent or antidote this poison directly. As for cutting off its source this is what we have been striving to do for years by accouchement forcé or at least by rapid delivery, which of course is not always practicable or available. Since the more convulsions the worse the outlook, it is right to suppress them by narcotics. Venesection with or without subsequent saline infusion is an antitoxic resource, since the woman can in most cases well undergo the loss of blood. Statistics show well that all three of these resources make for a reduced morality. In regard to emptying the uterus instantly both abdominal and vaginal hysterectomy have been recommended in recent years and the statistics of Dührrsen show practically no operative mortality so that there is no increase of risk. The loss of blood has only the force of a venesection and hence two of the three resources are combined at once. But vaginal hysterotomy must be done by an expert with trained assistance and under favorable conditions. The family practitioner can do no more than expedite labor and add to this a venesection and the narcotic method of Stroganow. Even these measures made a good statistical showing. Rapid delivery naturally implies a variety of procedures depending on the case. The narcotic method goes well with methods for operative delivery, as version and extraction, high forceps, etc. Our three main resources back one another up admirably, so that instead of competition numerous combinations are possible.

**Functional Affections of Arteries.**—Brunton mentions the small amount of space devoted to this subject when compared with the same type of maladies of the heart. He first takes up the phenomenon of abdominal pulsation which is compatible with the utmost integrity of the heart and blood vessels. It is doubtless of nervous origin and may be a reflex, as from a gastric or duodenal ulcer, and it certainly may accompany these conditions, as melena has been noted as an associated phenomenon. It need not be limited to the aorta, for in severe cases it involves some of the principal branches. In some such cases we may suspect a hyperthyroid factor. The change in the pulsations partakes of the nature of a widening of the vessel. There is evidence that this change in the calibre of the vessels may be produced in several different ways. One cause is the menopause. In some cases of migraine the carotid of the affected side may be felt to beat strongly. Naturally there is an opposite class of conditions in which the arteries may show contraction of a functional character but only peripheral vessels are concerned. It does not appear that the larger trunks are correspondingly involved or at least we have no knowledge of such affections. Clinical evidences of peripheral arterial contraction, may as is well known, simulate the various types of arteriosclerosis. In most cases of contraction of the peripheral vessels we find the blood pressure elevated, which would in fact be a natural result of such contraction. The latter causes ischemic conditions of various local organs which are often relieved by vasodilator remedies such as overcome the peripheral contractions and thereby lower the blood pressure. Some confusion must arise at times between a primary dilatation of the large trunks with secondary dilatation of peripheral internal arteries, and the elevation of blood pressure which results from contraction of the same vessels. Certain cases of headache, gastroenteric crisis, etc., may be diagnosticated only through the remedies which antagonize them. In pulsation of the large trunks with flushing of the face we have a condition very difficult to control. Many remedies are employed and probably the best results come from hygiene (rest, diet, laxatives), with simple sedatives like bromides and valerian.

**Barlow's Disease at the School Age.**— Glaser relates a case as follows: A boy aged six years was taken with pains in all his limbs which were successively involved. He was naturally regarded as a subject of rheumatism and was treated with aspirin. He became worse and developed gingivitis; and was removed then from his home to a hospital. It was learned that he had been living chiefly on bread and boiled milk. He was found to have hematuria and was pale. The joints were intact. The boy habituated to his meagre regimen refused eggs, meat, etc. A diagnosis of Barlow was made, and improvement at once followed the use of raw milk and orange juice. All the symptoms, due apparently to escape of blood, began to recede, and with abatement of pain and soreness the boy began to move about somewhat and the rheumatoid pains to vanish, completely functional recovery being somewhat tedious, being over three months deferred. The author states that this case will be regarded by some as old fashioned scurvy, of course by those who regard the two diseases as identical. Rickets can surely be ex-

cluded and as for syphilis the W.R. was quite negative. While Barlow's disease is preeminently one of infancy, like most diseases of such incidence, it must be able to appear at times at a remote period.

*January 28 and February 4, 1913.*

**Spasmogenic Peptic Ulcer.**—Von Bergmann first discusses vagotonus and its coexistence in part with sympathicotonus, and alludes to vagasthenia and sympathicasthenia. These conditions are to a certain extent hypothetic. Coming to the subject of ulcers ventriculi he states that it very often occurs with an abnormal reaction of the visceral nerves. We frequently see these ulcers in vagotonic subjects. The hyperacidity, increased stomach tonus, and increased peristalsis suggest vagotomy, and even pain is usually marked in these cases. There are other ulcers in which there is no evidence of the vagotonic syndrome. Another manifestation of the latter is the glistening eye and slight exophthalmos which is present in a large proportion of cases. Other symptoms are cold, moist hands, tremor, tendency to spastic constipation. Dermographism, swollen throat, and other vasomotor symptoms are sometimes seen. Pilocarpin causes a vagotonic picture in part, especially sharp pains in the stomach. The author, however, sees in the entire picture some evidences of sympathicotonus—exophthalmos and tremor. Of 60 cases of spasmogenic ulcers ventriculi and duodeni, all but two were in markedly neurotic subjects. A typical case is cited. Male aged 39 suddenly attacked with cramps in the stomach, and pressure which did not wholly disappear. Later "causeless" vertigo and prostration. Movements of tarry appearance. Vomited fresh red blood. Constipation then developed—with sheep dung movements. When examined showed pallor, collapse pulse (results of loss of blood). Slow recovery. Trial breakfasts and *x*-ray photos with other data gave evidence of gastric ulcer with occasional gastric spasm. There was great disturbance of both the sympathetic and vagus systems expressed by a variety of symptoms. The author devoted much reasoning to illuminate the rationale of these conditions, but the use of the term spasmogenic ulcer shows that he regards the gastrospasm as a cause and not an effect of the ulcer. Repeated spasms cause areas of ischemia in the gastric mucosa, and eventually erosions and ulcers are produced. Correspondingly for the prevention and arrest of these ulcers he recommends atropin as an antispasmodic. The use of this remedy should be prolonged and conjoined with the customary diet.

**Pregnancy Toxicosis Cured by Ringer's Solution.**—Eichmann describes several cases of gestation toxicodermiæ cured in this fashion. They are similar in type to those which have been cured by serum of gravidæ, horse serum, etc. The pruritus, so distressing in these cases, usually subsides promptly. From 100 to 200 c.c. of solution were slowly injected into the gluteal muscles. In a prior series of cases, the solution was given by infusion. The results were equally favorable but the injection technique is simpler. The gravidæ at the author's clinic are placed upon a vegetarian diet, apparently on the theory that the toxic material proceeds from the intestine —that is when the toxemia is expressed as an eruption. This view is based in turn on the relationship between alimentary intoxication and urticaria, and the fact that a vegetarian diet antagonizes the development of these alimentary eruptions. The author seeks to antagonize the placental theory of toxemia, and as she does not mention Abderhalden's recent work on placental albumin and the diagnosis of pregnancy, it is evident that she is not in position to criticise this view which according to good authority has now passed the controversial stage.

**Sterilization and Sociology.**—Hegar cites a number of cases of women who had gradually become insane, and who meanwhile had become pregnant by their husbands, against the warnings of asylum directors. Not only were the children menaced, but the mental health of the mothers was further prejudiced. Sterilization would have prevented such situations but the first and simple duty was to proceed against the husband who was the sole offender. He opposed incarceration and with one excuse or another sought to have the wife under his personal charge. Every one of four women described was impregnated by the husband after he had secured her release from the institution. The author seems opposed to sterilization of married women, for instead of proving a benefit to society the reverse result may follow. Had sterilization laws been in force in the past we should have had, for example, no Beethoven. His paternal grandmother was a hard drinker, as was also his father. Both father and mother were easy going. The father because of bad heredity and his own psychopathic tendencies might have allowed himself to be sterilized for the good of society. Problems frequently present themselves. A woman with insanity of gestation, and hysterical in disposition was incarcerated twice. The husband felt it his duty to procreate no more children and would have abstained from intercourse but the wife instantly became jealous and demanded coitus so that a third conception was the result. Then came an artificial abortion. In this, as in similar cases, sterilization of the husband seemed the rational course, and a simple means against the abortions, suicides, and murders which follow gestational insanity. The author as stated believes that females should be sterilized only in childhood. The sterilization of the male is another problem, more complicated. Aside entirely from the descendants there is another sociological aspect bound up in sexual crimes against the person. A single degenerate may assault and injure or kill a large number of persons, to say nothing of the social stigma cast on some of his woman victims. Sterilization in such cases might need to be absolute. Some of the worst of these men when they have money spend it on prostitutes which shows that an incurable sexual perversity exists. Others, however, the author says, are sufficiently sane to recognize their dangerous status in society and are glad to marry, if the opportunity presents.

**Thyreosis and Tuberculosis.**—Saathoff discusses the supposed association of these two affections with special reference to Graves' disease. There is a striking correspondence between the initial manifestations of the two. Among these are cardiac disturbances, vasomotor phenomena, tendency to perspiration, fever, vertigo, tremor, increased exhaustibility, insomnia, gastroenteric disturbances and emaciation. The two processes differ radically in their nature, and for a year and a half the author has instituted comparative studies. Previous writers had sought for the presence of the thyreotoxic factor in tuberculosis while the author studied his cases of Graves' disease for the presence of a tuberculous factor. He became astounded at his results. He examined the lungs in the usual manner and with the *x*-rays; took careful temperature measurements, invariably per rectum; used the von Pirquet and ordinary tuberculin reactions. At the same time his cases were examined as to the state of the thyroid and thyroid symptoms. The brief conclusions of his very prolonged study are that tuberculosis plays an essential rôle in the causation of thyreoses; the type of tuberculosis in these cases is usually the mild type with favorable prognosis. Rise of temperature when present is due to the tuberculous element. In any case whatever of hyperthyroidism we should investigate for tuberculosis.

### Deutsche medizinische Wochenschrift.

*January 23 and 30, 1913.*

**Metapneumonic Brachial Plexus Neuritis and Polyneuritis.**—Biermann first mentions the frequent occurrence of neuritis as a sequel of infectious diseases, which appears to be the result of the neurotropic action of the specific bacterial toxin. Very little is known of the intimate mechanism of the disease, the selective action of the toxins on particular nerve trunks, or the predisposition. Only after the existence of most of the other forms of post-infectious neuritis had been established did the metapneumonic form appear in literature. Naturally, cases are found here and there in the older literature but their nature was not fully recognized. In 1889 Oppenheim described a clean-cut example of symmetrical polyneuritis following pneumonia, but as the patient was an alcoholic this factor had to be taken into account. In 1890 Leech reported a case of multiple neuritis which appeared 4 or 5 days after the crisis of a pneumonia case and in 1893 Charcot described a similar existence. In both these cases all the extremities were involved. In 1893 Krafft-Ebing described a case of bilateral neuritis of the upper extremities and three years later Leszynsky saw a case involving the arm and shoulder muscles of both sides. Not until 1905 was there a case described of unilateral brachial neuritis, by Westphal. The infrequency of these cases makes it of unusual interest that the present writer has alone seen two cases of metapneumonic brachial plexus neuritis and one of polyneuritis within a relatively short time. The first case when summed up was that of a girl aged 24 who, ten days after typical pneumonia, experienced pain in both arms with subjective sensory disturbance, followed by severe paralysis in both arms, so that for three weeks she had to be fed. Five months later she showed pareses and atrophies in the regions of the thoracicus major, axillaris, subscapularis longus, suprascapularis, radialis and medianus of the right side, and similar distribution on the left side. While there were no objective sensory disturbances the case was regarded as one of neuritis. There was complete recovery at the end of two years. The second case agreed fairly well with the first. In the third case both lower extremities were chiefly affected, but there were also slight pareses, Biermann notes, in the upper extremities and in the parts supplied by the seventh cranial nerves.

**Cases of Cardiac Surgery.**—Lucas reports two successful cases of cardiac suture treated under unfavorable external circumstances. In the first case a jealous girl stabbed her rival with a letter opener. Twenty minutes later the victim was found in violent dyspnea with pains in the cardiac region. The wound was of course a mere puncture. There were no signs of cardiac activity, with great increase of area to percussion. Patient was at once slightly etherized and a fenestrated opening made in the thorax, which involved the ribs and cartilages from the third to the seventh inclusive. The pericardium was opened and blood and clots removed. The heart, hitherto passive, began to beat feebly. The small wound in the organ was sutured. As hemorrhage was not checked at once the organ was lifted from the thorax—whereupon it ceased beating—and examined on its posterior aspect. Nothing was found and when the organ was replaced it still refused to beat. The author then compressed and massaged it. Digalen was injected and within an hour the condition of cyanosis had passed off. It was necessary to dress a wound in the pleura, and the drain left within also drained the pericardium. The operation lasted but 18 minutes. Convalescence was stormy, as there was a secondry hemorrhage with filling of the pleural sac and a status of collapse which remained until the pleural exudate was finally disposed of. There were also acute symptoms due probably to pericardial adhesions, and others consequent upon the first attempts to get about. As a dramatic conclusion the patient married the man who was the cause of her predicament. The second case was one of a bullet wound. The ball had lodged in the liver after having traversed the heart. The openings made by the bullet in both ventricles were successfully closed by sutures.

**Tuberculosis of the Thyroid.**—Dutoit gives a brief digest of our knowledge of this subject which dates from the case recognized by Lebert in 1862. The secondary involvement of the organ was noted by various pathologists. No advances were made for years and it became recognized that the thyroid was one of the organs most rarely attacked, and that our entire knowledge of this localization was limited to autopsy finds. Not until 1893 was it reserved for a surgeon Bruns, to extirpate a caseous goitre. In 1897 Fränkel announced as the result of an analysis of recorded material that miliary tubercles are almost always present in the thyroid in general miliary tuberculosis, but that there was quite independent of this type, a nodular caseating form which seldom causes symptoms. According to Iwanow, who saw seven such cases this form is secondary to pulmonary phthisis. He applied the term tuberculous goitre to this form, in which, by the way, the thyroid functions are not compromised. In 1902 Clermont described an alleged case of primary tuberculosis of the thyroid in an infant, and shortly afterwards other authors followed with reports. Among these von Schiller reported a case of acute tuberculous strumitis. From another viewpoint tuberculosis is by no means uncommon in hypothyroidism, and in the absence of autopsy finds we cannot deny that the lesion of the gland which underlies some of these cases may not be tuberculosis. Conversely recent observers have much to say of the close relationship of tuberculosis and Basedow. The two conditions sometimes coexist in a manner not to be explained outright by coincidence. The tuberculous toxin may also have a tendency to stimulate the functions of the thyroid, so that a slight hyperthyroidism may often be noted in the consumptive, as evidenced in the tachycardia. Some authors go so far as to recognize a slight enlargement of the thyroid in these cases. This is the teaching of Poncet. Hedinger, rejecting this teaching, admits that dysthyroidism may coexist occasionally with tuberculosis, but only because actual lesions develop in the gland.

**Nature of Rickets.**—Kassowitz reiterates his well-known views, defending them from the attacks of others. Three postulates he thinks should be acceptable to all. First, pronounced rickets, affecting the cranial bones, is occasionally encountered in the healthiest looking and best fed babies. Second, in the warm summer months, in which digestive troubles flourish, the rickets curve sinks to its lowest point, likewise the so-called spasmophilic phenomena. Conversely in the cold months in which children eat better and are less burdened with digestive troubles, all these conditions have their acme of incidence. Third, in tropical countries we see hardly any rickets. Similar finds are obtained from a study of animal life. Having thus discredited the nutrition theory the author calls attention to the frequency of fetal rickets and of congenital evidences of the same. These cases may not as a class, be recognized outright as rickets but the softness of the cranial bones, the beading of the ribs, etc., seen perhaps as isolated lesions incline to rachitism. In the great majority of cases these are not recognized at first, and only in later years do the symptoms become prominent. This origin *in utero* does away completely with the alimentary theory of rickets, and we are therefore forced to substitute a respiratory theory. This the author does not elaborate, being content to connect rickets with "respiratory noxæ."

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### ELEMENTARY PRINCIPLES OF LIFE INSURANCE.

It is not essential to the success of examiners that they be proficient in the technicalities of the science of life insurance, but they will find their work more interesting and will be in a position to take a broader view of the many requirements if they have at least some general idea of those elementary principles of this complicated subject which are most commonly encountered by them.

The principles involved in the computation of the premium are the most important and are based upon the scientific combination of the tables of mortality with the tables of interest.

*The Mortality Tables:*—It was discovered practically in the beginning of the nineteenth century that there is a natural law governing the mortality of the human race, whereby it is possible to determine approximately, in a large group of persons, the number that will die in each year until all are dead. When this law became established, the business of life insurance was revolutionized and mathematical calculations superseded the crude guesses of life and death upon which the primitive methods had hitherto been based. Tables were compiled which were further developed subsequently by the actuaries of America and Great Britain. The American Experience Mortality Table was constructed by Sheppard Homans while actuary of the Mutual Life Insurance Company of New York, and is used by practically all American companies in computing their premiums. The tables usually employed in Great Britain and Canada are those known as the Actuaries' or Combined Experience Table of Mortality.

The table begins with 100,000 lives, starting with the age of ten years. Of these, 81,822 will still be living at the age of thirty-five, of whom 732 will die during the year. This will leave 81,090 still living at the beginning of the next year at age thirty-six, while 737 of this number will die in the ensuing 12 months. In this way the table shows how many of the original 100,000 are living at each age from ten years on, and how many will die in each year thereafter until the last three, who have lived to the age of ninety-five will die during or at the end of that year at the attained age of ninety-six. If a policyholder lives beyond the age of ninety-six, the companies, as a rule, will excuse him from the payment of further premiums.

THE AMERICAN TABLE OF MORTALITY

| Age | Number Living | Number Dying Each Year | Age | Number Living | Number Dying Each Year |
|---|---|---|---|---|---|
| 10 | 100,000 | 749 | 53 | 66,797 | 1,091 |
| 11 | 99,251 | 746 | 54 | 65,706 | 1,143 |
| 12 | 98,505 | 743 | 55 | 64,563 | 1,199 |
| 13 | 97,762 | 740 | 56 | 63,364 | 1,260 |
| 14 | 97,022 | 737 | 57 | 62,104 | 1,325 |
| 15 | 96,285 | 735 | 58 | 60,779 | 1,394 |
| 16 | 95,550 | 732 | 59 | 59,385 | 1,468 |
| 17 | 94,818 | 729 | 60 | 57,917 | 1,546 |
| 18 | 94,089 | 727 | 61 | 56,371 | 1,628 |
| 19 | 93,362 | 725 | 62 | 54,743 | 1,713 |
| 20 | 92,637 | 723 | 63 | 53,030 | 1,800 |
| 21 | 91,914 | 722 | 64 | 51,230 | 1,889 |
| 22 | 91,192 | 721 | 65 | 49,341 | 1,980 |
| 23 | 90,471 | 720 | 66 | 47,361 | 2,070 |
| 24 | 89,751 | 719 | 67 | 45,291 | 2,158 |
| 25 | 89,032 | 718 | 68 | 43,133 | 2,243 |
| 26 | 88,314 | 718 | 69 | 40,890 | 2,321 |
| 27 | 87,596 | 718 | 70 | 38,569 | 2,391 |
| 28 | 86,878 | 718 | 71 | 36,178 | 2,448 |
| 29 | 86,160 | 719 | 72 | 33,730 | 2,487 |
| 30 | 85,441 | 720 | 73 | 31,243 | 2,505 |
| 31 | 84,721 | 721 | 74 | 28,738 | 2,501 |
| 32 | 84,000 | 723 | 75 | 26,237 | 2,476 |
| 33 | 83,277 | 726 | 76 | 23,761 | 2,431 |
| 34 | 82,551 | 729 | 77 | 21,330 | 2,369 |
| 35 | 81,822 | 732 | 78 | 18,961 | 2,291 |
| 36 | 81,090 | 737 | 79 | 16,670 | 2,196 |
| 37 | 80,353 | 742 | 80 | 14,474 | 2,091 |
| 38 | 79,611 | 749 | 81 | 12,383 | 1,964 |
| 39 | 78,862 | 756 | 82 | 10,419 | 1,816 |
| 40 | 78,106 | 765 | 83 | 8,603 | 1,648 |
| 41 | 77,341 | 774 | 84 | 6,955 | 1,470 |
| 42 | 76,567 | 785 | 85 | 5,485 | 1,292 |
| 43 | 75,782 | 797 | 86 | 4,193 | 1,114 |
| 44 | 74,985 | 812 | 87 | 3,079 | 933 |
| 45 | 74,173 | 828 | 88 | 2,146 | 744 |
| 46 | 73,345 | 848 | 89 | 1,402 | 555 |
| 47 | 72,497 | 870 | 90 | 847 | 385 |
| 48 | 71,627 | 896 | 91 | 462 | 246 |
| 49 | 70,731 | 927 | 92 | 216 | 137 |
| 50 | 69,804 | 962 | 93 | 79 | 58 |
| 51 | 68,842 | 1,001 | 94 | 21 | 18 |
| 52 | 67,841 | 1,044 | 95 | 3 | 3 |

How does the table apply? For the sake of simplicity and convenience, let it be supposed that a company starts with 81,822 people, all at the age of 35, who wish to arrange for the payment of $1000 to their executors at death, and each of whom will maintain his membership during his entire life. The ultimate sum to be paid out amounts to $81,822,000 and must come from the premiums paid by the members and the interest these premiums will earn. How large a premium must each member pay in order to create a fund sufficient for this purpose?

The first step is to determine how large a total fund the company must have on hand at once to accomplish the payment of each policy to the end, without the necessity of adding new members or the so-called influx of "new blood"—an essential principle in the construction of regular insurance companies as distinguished from assessment societies.

By consulting the table again, it is seen that the 81,822 members will all die within the next sixty-one years. If there were means of knowing when any one individual of the group will die, the computation of his premium would be very simple. The table does tell, however, how long certain groups of the members will live. For example: at age thirty-five it is seen that 732 members will live only one year; that 812 will live ten years to age forty-five; 1470 fifty years to age eighty-five, and that the last three will live sixty-one years to age ninety-six. The computation of the premium must be based, then, upon the aggregate number of lives—the length of time the members will live as a body, as shown in the case of the different groups.

By continuing on in the case of the group of 812 members who will die during or at the end of the tenth year, at the attained age of forty-five, it is apparent that $812,000 will be required in the tenth year to pay the policies of $1,000 each. This amount is not demanded immediately, however, as it is only necessary to start with a sum sufficient with the addition of the earned interest in ten years to amount to $812,000. The computation has now reached the point where the interest tables must be consulted in order to ascertain the amount of the total fund which should be collected at once.

The object of this chapter is to emphasize the importance of the mortality table before taking into account the benefits derived from interest and the necessary expenses of transacting business. If there were no reliable table of experience for guidance as to the number of insured people who will die each year, the companies would find it an impossibility to adjust the premiums so that they would not be too large, or, worse, too small to provide sufficient funds for the ultimate claims.

The tables of interest and their bearing will be discussed in the next article.

# Book Reviews.

Sex Education. By Ira S. Wile, M.S., M.D. Price $1.00. New York: Duffield & Company, 1912.

The medical profession has become impressed by the need for a certain amount of education regarding sex and sex hygiene to be imparted to the rising generation. The general public appear to be now following this lead and consequently from all parts of the country demands have come and are coming that sex hygiene should be made a part of the school curriculum. The obstacles in the way of carrying out this plan are that no scheme has been formulated as to the nature and extent of this sex education. The work by Dr. Wile was conceived and written with the view of suggesting the scope and limits of such teaching. He has succeeded admirably in his object.

Manual of Human Osteology. By A. Francis Dixon, M.B., Sc.D. University Professor of Anatomy and Chirurgery, Trinity College, Dublin. Illustrated with 178 figures, many in colors. Price $3.00. New York: William Wood and Company, 1912.

This manual gives a very thorough description of the bones of the human body; it is a scientific and scholarly piece of work. The names adopted by the Basle Nomenclature Committee have been largely used, but other names in frequent use are also given. We fear that the present volume will not render the study of osteology less dry or more popular, for the author's style is not calculated either to awaken or to maintain interest in the subject. In this respect this book is the antithesis of Holden's charming volume on the same subject.

A Practical Medical Dictionary of Words Used in Medicine with Their Derivation and Pronunciation, Including Dental, Veterinary, Chemical, Botanical, Electrical, Life Insurance and Other Special Terms; Anatomical Tables of the Titles in General Use, and Those Sanctioned by the Basle Anatomical Convention; Pharmaceutical Preparations, Official in the United States and British Pharmacopœias and Contained in the National Formulary; Chemical and Therapeutic Information as to Mineral Springs of America and Europe, and Comprehensive Lists of Synonyms. By Thomas Lathrop Stedman, A.M., M.D., Editor of "Twentieth Century Practice of Medicine;" Editor of the Medical Record. Second Revised Edition. Illustrated. Price, $4.50 net, plain; $5, indexed. New York: William Wood & Company, 1912.

This work appears to have received more extensive additions than it is the custom to make in a book in its first year of life. It is stated that the old plates were destroyed, thereby giving the author the opportunity to make any changes he found to be desirable without reference to what the cost of such revision would ordinarily be. He has evidently taken advantage of the free hand this offered him, for in the preface it is said that over 2,000 new titles have been inserted, the typographical errors in the first edition have been corrected, the biographical data have been brought down to date, and a table of symbols has been added to the appendix. In style and general appearance this edition is practically the same as the first, except that a red cover has been substituted for the green one in which the book first appeared.

Atlas der Operations-Anatomie und Operations-Pathologie der Weiblichen Sexualorgane, mit Besonderer Berücksichtigung des Ureterverlaufes und des Suspensions und Stützapparates des Uterus in 35 Tafeln. (Atlas of the Surgical Anatomy and Pathology of the Female Sexual Organs, with Especial Reference to the Course of the Ureters and the Suspensory Apparatus of the Uterus.) By Dr. Wilhelm Liepmann, Berlin. Thirty-five plates, with explanatory text. Price, 24 marks. Berlin: August Hirschwald, 1912.

The author of this very valuable atlas has already become well known by his previous gynecological and obstetrical manuals. His aptitude in producing clarifying illustrations is again well shown in the work herewith noted. The pictures are taken from preparations which have been hardened in formalin or by freezing methods. They are reproduced in life size, and correspond to the wax models which the author exhibited at the recent International Gynecological Congress. Although surrounded with unavoidable restrictions which are due to the exigencies of the methods of preparation, the pictures as a general thing, if submitted to analysis and study, afford an excellent and clear idea of the anatomical region in question. They require very careful attention, however, but the trouble will be amply repaid. The relations of the floor of the pelvis are particularly well demonstrated. In a separate folio is presented an explanatory text which aids greatly in the understanding of the pictures. The work constitutes a very valuable addition to gynecological literature.

Gould and Pyle's Cyclopedia of Medicine and Surgery. With Particular Reference to Diagnosis and Treatment. Second Edition, Revised and Enlarged. Edited by R. J.E. Scott, M.A., B.C.L., M.D. Price $12.00. Philadelphia: P. Blakiston's Son Company, 1912.

This work, which is a compromise between a dictionary and an encyclopedia, was originally devised after the plan of the one-time most popular Quain's Dictionary of Medicine, but extended to include surgery and the various specialties. The only other work in this special field to-day is the volume edited by J. Keoch Murphy and published by the Oxford University Press. The plan of the book is that of a cyclopedia, the titles being arranged alphabetically instead of by subjects as in the usual "System." Such a plan is convenient for reference, but when carried to the extreme, which it is here, without page numbers and with no index, it often defeats its own end; for unless the reader is in telepathic accord with the editor and turns at once to the title which the editor had in mind in laying out the work he is likely to be disappointed in his quest. The editors have indeed sought to remove this difficulty by a system of cross-references, but this is necessarily imperfect and is not an acceptable substitute for an index. The reviewer has looked in vain for articles on the Hypophysis cerebri, Infantilism, Nauheim treatment, Pineal gland, Progeria, Radiotherapy, Thalamus syndrome, Thorium, and other subjects. Doubtless these are treated of somewhere in the volume, but buried treasures are of little use, especially to the man who has not the time to dig for them. This defect is the more regrettable, for the articles that are available are as a rule excellent of their kind and give the reader just what he wants to know of the subject with the least expenditure of time and labor. To facilitate reference much of the information is given in the form of the well-arranged tables taken for the most part from the "Illustrated Dictionary of Medicine" by the senior editor.

This second edition is the work of thirty-three contributors, whose names are given on the title page but who are otherwise anonymous, since the articles are not signed. In the preface to the first edition the editors state that they have changed the several contributions so as to make them conform to their own ideas. The advantage of this plan is that it means more or less uniformity of treatment of the various subjects, but its obvious disadvantage is that the statements rest no longer upon the authority of the contributors, who are supposed to be experts in their respective lines, but entirely upon that of the editors, who cannot pretend to omniscience. If they are humble, as all editors should be, such remodelling will work no harm, but if they are arrogant, as some editors unfortunately are, the possibilities of error in statement are great and disquieting to the seeker after knowledge.

Apart from, and in spite of, those defects in plan, the work is deserving of the highest commendation. It is truly encyclopedic in character, embracing the whole realm of medicine, and the omissions are few—fewer even, no doubt, than they appear to be owing to the lack of an index. The articles are succinct and informing and the reader feels assured that he has presented to him all the facts that it is essential for him to know, unless indeed he wishes to master the subject, in which case he would naturally turn to a larger and more comprehensive work or to a special treatise. As the editor of the second edition puts it, "The purpose of the present edition of this Cyclopedia is to provide the general medical reader with a source of information on every medical subject except his own specialty." With the limitations above noted, this purpose has been successfully attained.

Der gerichtlich-medizinische Nachweis der wichtigsten Gifte. Von Prof. Dr. med. Hermann Hildebrandt, Privatdozent für Pharmakologie und gerichtliche Medizin an der Universität Halle a. S. Price 2 M. Berlin: August Hirschwald, 1912.

In this small work Hildebrandt presents a rather exhaustive discussion of the methods for the medicolegal recognition of the most important poisons. The first portion is devoted to general considerations of symptoms, autopsies and the manner of obtaining specimens. The reader will get an illuminating insight into the exacting requirements of the German law, but as a whole the matter is rather chaotically arranged. In the remainder of the pamphlet are found described the methods recommended for the recognition of the individual poisons. This portion of the work is excellent. Biological and chemical tests are given in great numbers and their relative values carefully considered. The index is unusually inadequate, even for a German publication.

# Society Reports.

## REPORTS OF THE TUESDAY CONFERENCE OF THE NEUROLOGICAL INSTITUTE OF NEW YORK.

*First Division.*—Dr. Joseph Collins.

**Brain Tumor.**—Dr. Collins, in presenting this case, said that it was an uncommon experience to have the symptoms of organic brain disease conclusive regarding the location of the lesion. He, therefore, thought it worth while to exhibit a patient who presents such symptoms. Intracranial surgery is still an uninviting field compared with spinal surgery because of this uncertainty of localization, and because of the frequent disappointments that we encounter when the cranium is opened for the relief of disease whose location has been diagnosticated with much confidence.

The patient, a man forty-one years old, encountered when he was thirty-four years old, what was construed to be a mild injury to the head. He was walking out of a cellar when the right side of his head behind the forehead came in contact with a projecting beam. He was dazed and dizzy for a short time afterward, but he kept at his work and worked the next day. Indeed, it was not until after the present illness developed, *i.e.* four months after this accident, that he gave the injury any particular thought. The initial symptom of his disorder which brought him to the Neurological Institute, November 25, 1912, occurred in the evening just after he had finished taking a foot bath. According to his wife's statement, he fell backward on the bed and then the left hand and arm flexed and extended rapidly. The spasm then extended to the leg, and finally involved the head. She recalls that the head was turned to the left and the eyes upward and to the right. The duration of the attack was not longer than five minutes, and during this period he was entirely conscious and conversed with his wife. He went to work the next day and there is no history of impaired motility either of the arm or of the leg. The next attack occurred one month later, and, so far as can be learned from the patient and from his family, it was a parallel of his first attack. Neither of these attacks was considered of any great importance, nor was a physican summoned. The third attack, and the one from which he dates his present incapacity, occurred about a year after the second, and that is somewhat more than four years ago. This attack was likewise apparently a typical attack of Jacksonian epilepsy, but he became unconscious after it and remained unconscious or stuporous for several hours, and following this, he was heavy and lethargic for one or two days. After this attack he noticed that his left lower extremity was weak, stiff, and unwieldy. The left hand at this time did not show any considerable loss of strength or of dexterity. He kept at his work which was that of a peddler. In four or five months he had the next attack, and after that attack his leg became more feeble and his left hand showed from that time on some loss of dexterity.

His complaint on presenting himself to the clinic was inability to walk normally and securely; inability to use his left hand with the same readiness as his right, and attacks occurring at infrequent intervals, usually not accompanied by loss of consciousness and which will be described in greater detail below; frontal headache, occasional attacks of vertigo, a sense of apprehension, confusion, and fear. Examination shows: (1) Partial left hemiplegia with all of the concomitants of an organic lesion, *i.e.*, plus tendon jerks, Babinski phenomenon; (2) complete astereognosis of the left hand; (3) loss of the deep sensibility in the entire left side of the body and extremities; (4) slight but distinct hypesthesia and hypalgesia of the left side of the body and of the extremities; (5) absence of the abdominal, and epigastric reflexes of the left side; (6) complete homonymous hemianopsia; and no other physical signs. He was brought into the hospital for fuller examination and laboratory investigations which, however, were negative. During the time that he was in the hospital he had two attacks of Jacksonian epilepsy. They began by his shouting, "Help me! Help me!" There was then noticed a spasm in the muscles of the left hand, clonic convulsion of the muscles of the hand, the forearm, and drawing up of the leg and the thigh, and the rotation of his head toward the right with queer pouting movements of the lips and blowing expiratory movements of the mouth and face. When these clonic spasms, which occurred three or four times a second, were relaxed, very extraordinary manege movements would occur. These movements resembled somewhat the gesticulations which one not infrequently sees in dementia præcox. At first sight they looked very much as if he were attitudinizing. The fingers of the left hand would flex, the index finger, and then the forearm, would be extended as though he were going through some dramatic performance; at another time the hand would assume a position of the accoucheur hand; at another time the forehead would wrinkle laterally, the eyes take on a severe expression while he would pout and blow rapidly a number of times in succession. During all this time, that is, during the display of the clonic spasm and the manege movements, he was apparently quite conscious, and when the spasm would permit him to do so, he would converse and answer questions. The whole attack lasted about ten minutes.

These attacks taken in conjunction with the objective symptoms above enumerated, and particularly taken in conjunction with the cardinal symptoms of brain tumor present; that is, frontal headache, vertigo, and sense of confusion, makes the diagnosis of brain tumor quite justifiable.

It is believed that the lesion responsible for the symptoms in this case is situated in the Rolandic region and extending into the substance of the brain to such an extent that it interrupts the radiations of Gratiolle in the right hemisphere or backward through the inferior parietal convolution to disrupt the continuity of the fibers coming from the right cuneus to pass forward and downward into the optic chiasm. The primary symptoms were apparently entirely motor irritation phenomena—attacks of Jacksonian epilepsy. The second symptom was a motor destructive phenomenon, and partial hemiplegia, both pointing toward irritation and encroachment upon, but not destruction of, the anterior central convolutions. The third symptom, viz., loss of the deep sensibility; and likewise the fourth and fifth, viz., astereognosis and the loss of the abdominal and epigastric reflexes indicating an extension backward into the middle part of the posterior central convolution, while the left-sided hemianopsia indicated a further extension backward to involve the optic radiations.

It is regrettable that a case in which the localization can be made with such apparent accuracy should not be willing to subject himself to operation, but as was said in the beginning, the patient resolutely objects to it and purposes leaving the hospital to-day.

Second Division—Dr. Frederick Peterson.

**Polioencephalitis.**—Dr. Peterson presented the following case: G. C., female, age 27 years. This patient was admitted to the hospital on September 14, 1912, complaining of paralysis of the eyeballs and occasional difficulty in speech. Her previous history is—she is of English birth but has lived almost her entire life in British Guiana. Beyond frequent malarial attacks, her health has been good. In 1897 she noticed that her eyelids drooped. This persisted. In 1901 she was seen by an oculist in Edinburgh and was told that her eyeballs were "station-

ary," a fact of which she had previously been in complete ignorance, though most probably it had been present for some considerable time before its discovery. In 1910 her voice began to alter, assuming frequently a nasal quality. In 1911 she began to have difficulty in swallowing, inasmuch as rapid attempts at swallowing fluids resulted often

Fig. 1.—A case of polioencephalitis.

in regurgitation through the nose. Of late she has had a persistent feeling of weakness and fatigue, which does not rapidly develop nor rapidly subside on rest. All her symptoms have persisted and slowly progressed. She has occasional "pins and needles" sensation in her feet and a dull aching pain in the legs. She also complains of frequent numbness and "deadness" in the arms and hands and of late an almost daily nausea. There has been no sphincter trouble. In the five months preceding admission she lost 25 lb. in weight. In spite of her account of loss in weight, the patient has a well nourished appearance. Her facial expression is listless, this being produced by well marked ptosis of both eyelids. The eyeballs are fixed, *i.e.*, there is complete bilateral external ophthalmoplegia. Her voice is "thick" and distinctly nasal in tone; there is considerabl edifficulty in pronouncing words containing "r."

Pulse 74 per min. Blood pressure 114. The ocular fundi are normal. The pupils are equal, of regular outline, central in position and of brisk reaction to light. The intrinsic eye muscles are as above described. The muscles supplied by the seventh nerves are normal. The left masseter is atrophic, as are also both sternomastoid muscles. There is no objective weakness nor wasting elsewhere in the body. No tremor; no ataxia. Gait and station normal.

The arm jerks, knee jerks and ankle jerks are present and equal on either side. The plantar reflexes have been rather variable, that on the right side being several times of extensor type. The abdominal reflexes are sluggish but equal on either side. There is no loss of power to appreciate temperatures nor touch stimuli. Pin prick is felt more acutely on the left than on the right side of the trunk. Electrical reaction showed diminished excitability in the left masseter and in both sternomastoid muscles. In none was there any suggestion of a myasthenic reaction. No abnormal changes have been found by serological examination of the blood and cerebrospinal fluid.

Possible diagnoses in this case are: (1) Chronic superior polioencephalitis; (2 syringobulbia; (3 myasthenia gravis.

Of these, the first is the most probable in spite of the great slowness in progression. The disease known by this name might with advantage be termed in words more truly indicative of its exact pathology. The lesion is degenerative rather than inflammatory; such degeneration being produced by simple lack of vitality or through the action of a specific and selective toxine as yet unknown and its place of incidence being the nuclear elements in the bulb. Cavity formation or gliosis in the bulb must be considered because of the possible change in the type of plantar reflex and the dulling in power to appreciate pain stimuli. However, the evidence of involvement of the fillet and the pyramidal tracts is so slight as to be inconsiderable. The facial aspect of this patient, is that of myasthenia gravis, but the presence of definite muscle atrophies, the absence of specific electrical reactions, and the very slow and steady progress of the disease, furnish strong discounting arguments.

### Third Division—Dr. Pearce Bailey.

**A Case of Pure Alexia, with Localization Confirmed at Operation.**—Dr. Louis Casamajor presented this case:

Following Wernicke's original work on the cerebral localization of speech function and lesions causing aphasia, there were many attempts to divide and subdivide the classification and demonstrate lesions responsible for the different forms. Of all the forms of language function disturbance there is no more definite picture than that of alexia—an inability to read or understand written language. From a study of autopsy material Déjérine offered the hypothesis that there exists in the brain a definite reading center, i.e., a center of visual word memory which he placed in the angular gyrus on the left side. This author divided alexia into two forms: (1) alexia (word blindness) with agraphia or marked writing defect; (2) pure alexia with integrity of writing both spontaneous and on dictation.

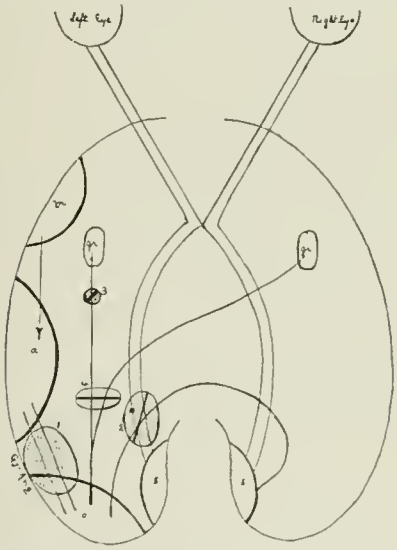

Fig. 2.—Diagram showing locations of lesions causing alexia. (From Liepmann.) *a*, Sensory (acustic) speech area. *m*, Motor speech center. *o*, Center for optic memories. *s,s*, Visual centers (calcarine cortex). *gr*, Writing centers for right and left hands. *Gyr. Ang.*, Angular gyrus. Lesion 1 causes alexia and agraphia. Lesion 2, pure alexia with hemianopsia. Lesion 3, pure agraphia of only the right hand. Lesion 4, pure agraphia of both hands.

Form 1, he considered due to a lesion in the angular gyrus destroying visual word memory, thus preventing the comprehension of written words and the production of them.

Form 2, he thought due to a subcortical lesion under the angular gyrus destroying the fibers going to it from the optic center.

Liepmann does not recognize the existence of a special center for visual word memory and his explanation of the location of these lesions will be seen in the accompanying diagram, Fig. 2. Alexia and agraphia, according to Liepmann, may be caused by a lesion in the angular gyrus, but it does so because it interferes with the communication between the sensory speech center (a) and that of optic memories (o). This prevents the understanding of reading as it interrupts the path o-a and also makes writing impossible, as the path a-o-gr. is no longer functionating.

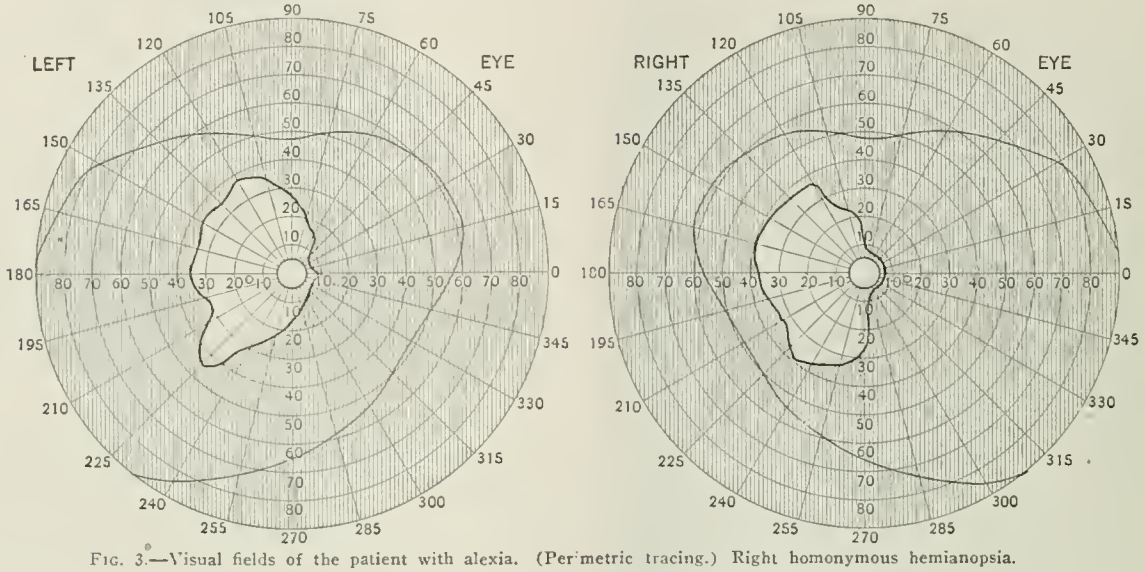

Fig. 3.—Visual fields of the patient with alexia. (Perimetric tracing.) Right homonymous hemianopsia.

Pure alexia which is practically always associated with right homonymous hemianopsia is caused by a lesion lying deep in the substance of the left occipital lobe pressing not only on the optic radiations but upon the fibers going from the calcarine area to the optic memory center (O). A glance at the chart shows that this would cause pure alexia with the writing function undisturbed as the path A-O-gr. is not interfered with.

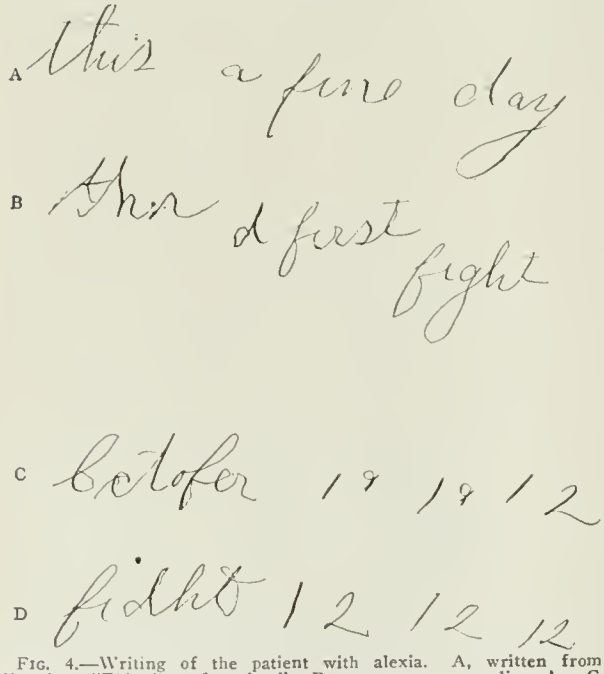

Fig. 4.—Writing of the patient with alexia. A, written from dictation, "This is a fine day." B, attempt to copy line A. C, written from dictation, "October 19, 1912." D, attempt to copy line C.

The case here reported is of interest from the point of view of localization in view of the conflicting opinions above expressed.

S. C., American, carpenter, age 35 years, was sent to the Third Division on October 17, 1912, by Dr. E. J. O'Shaughnessy, of New Canaan, Conn., complaining of fainting spells, periodic attacks of headache and vomiting. The family history was negative and his early life uneventful. He denied syphilis. Three years before admission he had been struck on the head by a falling beam and rather severely injured. Following this he suffered from frontal and occipital headaches which increased in severity. Six weeks after the injury he underwent a frontal sinus operation which afforded him no relief.

In January, 1912, he began to complain of weakness in his legs, loss of ambition and failing eyesight. In April, 1912, he had his first attack of severe headache and vomiting lasting 3 or 4 days. After this he had three or four similar attacks of which little is known. On July 25, there was another attack of severe headache and vomiting after which he slept for two hours. On awakening he was confused and disoriented and thought he had been operated upon, which condition lasted less than twenty-four hours. From now on his headache was more or less constant and occasionally he vomited. On September 10, he became semiconscious, vomited, had hiccough and voided urine involuntarily. He could be aroused only with difficulty but was unable to answer questions. At this time, it was noticed that he had double choked discs. Two days later he had recovered but had no memory of what had happened. On October 5, his physician noted that he could not recognize many of the letters of the alphabet.

On admission here on October 12, he showed slight swaying in gait and station and some intention tremor of the arms and legs. All deep and superficial muscle reflexes were active and equal. No clonus or Babinski. There was neither sensory disturbance nor ataxia. Dr. Holden's examination of his eyes showed unequal pupils. The right pupil was sluggish to light, left O. K. Ocular movements normal, no nystagmus. Right homonymous hemianopsia, not even light being perceived (Fig. 3). There was papilloedema of 2 D in each eye.

Speech function examination showed a very slight degree of sensory aphasia in that there was some paraphasia on spontaneous speech and he failed to name some common objects correctly. The most prominent feature of the case was a complete alexia without disturbance of faculty of writing. He was unable to name the letters of the alphabet correctly calling G-L, K-N, C-R, F-E, H-Y, etc. He was unable to read the simplest words or to reognize such simple symbols as U. S. A., Y. M. C. A., Conn., N. Y., etc.

In the writing tests he wrote well spontaneously, making few mistakes. Writing from dictation was on the whole good, but he was unable to copy anything, even what he had written himself (see Fig. 4). His mentality was not impaired. He had clear insight into his aphasic disorder. He had no memory disturbance. He said and wrote the multiplication tables of 2 and 7 with accuracy.

His urine was negative. Serum Wassermann positive. Spinal Fluid: Glob. plus plus. Negative Fehlings. Cells 5 lymphocytes.

During his stay in the hospital the patient complained of continual severe frontal headache and frequently had projectile vomiting. On October 24 he received 0.6 grms. salvarsan. but no improvement followed. At times he was stupid and appeared irrational.

On November 6 he was noted as having a slight right facial weakness and some increase of deep reflexes on the right side. No Babinski.

On the diagnosis of occipital lobe tumor, Dr. Elsberg did an exploratory craniotomy on November 14, 1912. On opening the dura there was evidence of great intracranial pressure but no tumor was seen. An incision was made into the brain substance to the ventricle and considerable yellowish fluid escaped. By inserting his finger in the ventricle the surgeon felt a hard tumor mass in the mesial wall of the ventricle.

Following the operation the patient had a complete aphasia which gradually receded. All reflexes were diminished. He made a good post-operative recovery and now has a hernia over the skull opening.

Physical examination now shows hemianopsia as before, discs show no swelling. Reflexes the same as on admission except that possibly there is a slight increase of the right knee jerks. Aphasic status now shows considerable sensory aphasia. Spontaneous speech is markedly paraphasic. He is unable to name simple objects or to pick them out when told to. There is no agnosia or lack of understanding of speech. Although he cannot name a knife when he is shown one yet he knows how to handle it and takes his own knife out of his pocket to show he knows what it is. The alexia is still complete and he is also agraphic. In attempting to write his name, stops confused after writing his first name. He is unable to write even simple words on dictation. Copying is absolutely lost. His insight into his aphasia is still clear. Mental examination is impossible on account of the aphasia.

The position of the tumor in this case bears out the contention of Liepmann in regard to the causation of alexia. Lying as it does on the mesial wall of the ventricle it could cause very little pressure on the angular gyrus region. It corresponds accurately with Lesion 2 of Liepmann's chart. The sensory aphasia following the operation is certainly due to disturbances of the tempo-sphenoidal lobe coincident to the decompression.

# THE SEWERAGE PROBLEM IN NEW YORK CITY.

SUMMARY OF THE REPORT OF THE METROPOLITAN SEWERAGE COMMISSION FOR 1912 BY THE PUBLIC HEALTH, HOSPITAL, AND BUDGET COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.

Prepared by LINSLEY R. WILLIAMS, M.D.

A comprehensive report issued by the Metropolitan Sewerage Commission of New York in 1912 contains a description of the present sanitary condition of the harbor, and the degree of cleanness which is necessary and sufficient for the water.

An earlier report, published in 1910, showed three essential facts: (1) That the harbor was grossly polluted with sewage; (2) that this organic matter had drawn heavily upon the natural assimilative capacity of the water, and, (3) that the tidal action did not flush out the harbor, but each tide only partially refreshed the water.

The 1912 report contains a large amount of data published for the first time, with numerous tables and diagrams of the examination of dredgings from the harbor bottom, the numbers of bacteria in the water, and the amount of dissolved oxygen. The report describes the harbor as a part of the sea, consisting of the following arms or divisions: Lower Bay, Jamaica Bay, Arthur Kill, Upper Bay, Kill van Kull, Newark Bay, Hudson River, Lower East River, Upper East River, Harlem River—the total water surface being 210 square miles at high tide. The quantity of water in the harbor is large, but the net seaward discharge is relatively small. Twelve billion cubic feet of water enter the Narrows at each tide and thirteen billion, three hundred million cubic feet pass out, the excess flow to sea being only a little over 10 per cent. above the flow landward. The flow toward the Narrows through the East River, formerly thought to be large, was found to be negligible from the standpoint of sewage disposal.

The harbor received, in 1910, the discharges of 6,423,000 persons, amounting to 110,000,000 cubic feet of sewage per day, a large proportion of which entered the East River, making this arm of the sea the most heavily polluted of all the divisions of water comprising the harbor. The waters of the harbor continually showed the presence of large fields of floating sewage, oily sleek, and quantities of visible fecal matter. Some parts of the harbor, such as the Passaic River, Newtown Creek, Gowanus Canal, Buttermilk Channel, the Bronx River and the Harlem River, as well as parts of the East River, were always offensive to sight and smell.

The sewage is discharged through several hundred outlets located along the water front and is slowly diffused. Oxidation begins at once and some solid parts settle to the bottom, where the available oxygen soon becomes exhausted and putrefaction sets in.

As the flushing action of the tide is so slight, the organic matters are disposed of in the harbor water by a natural process of assimilation which the commission has termed digestion. The digestion is dependent on the oxygen content of the water and it is essential that there shall always be enough oxygen present to carry it on. If the supply of oxygen is ever allowed to become exhausted, the water will turn black, offensive gases will be given off and the harbor will resemble a huge septic tank.

In order to determine the oxygen content, investigations, lasting over a period of two years, were made, the water being examined in various parts of the harbor and at various depths. The 2,670 samples which were examined showed that the water, which at usual temperatures should normally contain roughly 6.4 c.c. of oxygen per litre, contained much less than this. The Narrows showed 64-89 per cent. of the normal, the mouth of the Hudson (opposite the Battery), 51-64 per cent., and the mouth of the East River, 50-64 per cent. The conditions varied, being usually better at high tide than at low tide and better in winter than in summer. Other examinations showed the amount of pollution in deposits on the harbor bottom and the numbers of bacteria in the water.

It seemed wise to the commission to establish a standard of cleanness, and to this end a number of experts were asked to advise with the commission: Prof. W. E. Adeney of Dublin, Ireland; Charles V. Chapin, M.D., Health Officer of Providence; Harrison P. Eddy of Boston; Desmond Fitzgerald of Boston; William P. Mason of Troy;

William T. Sedgwick, Professor of Biology in the Massachusetts Institute of Technology, Boston; F. Herbert Snow, Chief Engineer, Pennsylvania State Department of Health, and C. E. A. Winslow, Curator of Public Health, American Museum of Natural History.

The experts were of opinion that a provisional standard of cleanness was necessary and agreed with the commission that no one standard, either chemical or bacteriological, would be practicable, Prof. Adeney alone dissenting. This difference of opinion was more seeming than real. Dr. Adeney considered that all sewage should be thoroughly screened before being discharged into the harbor and that, if this was done, a chemical standard would be sufficient for the water. His standard would not permit the reduction of dissolved oxygen to less than 60-70 per cent. of saturation and an ammoniacal nitrogen content not exceeding 1-1½ parts per hundred thousand. The commission has published in full the reports of the various experts and has proposed the following standard.

1. Garbage, offal, or solid matter recognizable as of sewage origin shall not be visible in any of the harbor waters.

2. Marked discoloration or turbidity, due to sewage or trade wastes, effervescence, oily sleek, odor, or deposits shall not occur except perhaps in the immediate vicinity of sewer outfalls, and then only to such an extent and in such places as may be permitted by the authority having jurisdiction over the sanitary condition of the harbor.

3. The discharge of sewage shall not materially contribute to the formation of deposits injurious to navigation.

4. Except in the immediate vicinity of docks and piers and sewer outfalls, the dissolved oxygen in the water shall not fall below 3.0 cubic centimeters per litre of water,* Near docks and piers there should always be sufficient oxygen in the water to prevent nuisance from odors.

5. The quality of the water at points suitable for bathing and oyster culture should conform substantially as to bacterial purity to a drinking water standard. It is not practicable to maintain so high a standard in any part of the harbor north of the Narrows, or in the Arthur Kill. In the Lower Bay and elsewhere, bathing and the taking of shellfish cannot be considered free from danger of disease within a mile of a sewer outfall.

A careful reading of the report of the commission and its consulting experts makes it apparent that if conditions in the harbor are not promptly rectified, the waters will become so foul as to constitute a public nuisance. An important step toward the prevention of this nuisance is the establishment of a standard of cleanness. It is evident that in order to maintain the standard, much sewage must be kept out of the harbor. To accomplish this end, main drainage works must be built to carry the sewage from its present points of outlet to places where it can be disposed of without creating a nuisance or doing harm to the public health. These works will have to be constructed by a central board or commission possessing special powers, such as the New York Water Board possesses and such as were given to the Rapid Transit Commission which constructed the subway.

The term of life provided for the Metropolitan Sewerage Commission expires by statute May 1, 1913. The powers and functions of this board have been solely advisory. It has made many investigations and recommendations looking to the improvement of sewerage and sewage disposal. In addition to the work described in the large printed volumes of reports already referred to, the commission has made specific recommendations for the construction of main drainage works and sewage disposal plants for New York. The plans for these works have been issued in a series of preliminary reports of which five have thus far been printed.

It must be obvious to all who have followed the work of the commission that the time has come for the city of New York to follow the example of other large seaport cities and take steps to protect and improve the sanitary condition of the harbor. To the casual visitor to this city, as well as to the permanent resident, the custom of discharging the sewage under the present careless and unsystematic conditions offends the sense of decency and may involve grave sanitary consequences. What the conditions would be thirty years from now, if nothing was done to protect the harbor, is extremely unpleasant to consider. The population draining into these waters will be about twice what it is to-day and the evil consequences of pollution will be correspondingly increased.

In building extensive works for the sanitary disposal of its sewage, in accordance with the plans of the Metropolitan Sewerage Commission, New York will but follow the lead of practically all the great cities of the world, including London, Paris, Berlin, Hamburg, Bremen, Glasgow, Birmingham, Manchester, Southampton, Dublin, Belfast, Boston, Providence, Worcester, New Bedford, Baltimore, Philadelphia, Washington, Atlanta, and Chicago.

*With 60 per cent. of sea water and 40 per cent. of land water and at the extreme summer temperature of 80° F., 3.0 cubic centimeters of oxygen per litre corresponds to 58 per cent. of saturation.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held February 6, 1913.*

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

**The Care and Control of the Feeble Minded.**—The following resolution was offered, seconded, and carried: "We believe that the interests of the State and of the individuals concerned would be best served if the care of the feeble minded in the State of New York were provided for as follows, namely,

1. That the laws of the State be so altered that the entire charge of the feeble minded throughout the State be placed in the hands of a Board of Control. Such a board should have powers analogous to those residing in the State Board of Lunacy and should be responsible for the care of all feeble minded in the State from birth to death. They may, however, at their discretion, delegate the education of such children as are educable to parents and, in such communities as make proper provision for the care of the feeble minded, to the local education authorities during that part of the lives of such educable feeble minded children as come within the usual school ages.

2. Race, religion, and economic status should not relieve the family of a feeble minded individual from the supervision of the State authorities or the restrictions which it might be necessary to impose for the public welfare.

3. Before school age the care of the feeble minded would naturally fall to the family under the supervision of such a board, with or without the additional observation of private agencies.

4. During school age all educable children should be taught so far as possible to be self-supporting either by private means, or in existing public schools, or in special institutions if these means are later provided.

5. After school age, the feeble minded who are non-self-supporting should be cared for by the State or by private means under State supervision. Those who are self-supporting might be allowed under restrictions to live outside of institutions, but it should be the ultimate aim to supervise all feeble minded in or out of State institutions that the propagation of their kind may be prevented. To accomplish this result some kind of custodial care for women and men in farm colonies will have to be provided.

6. All of the feeble minded who come under the jurisdiction of the courts should be referred by the courts to the State Board of Control for detention and care, and to be separated from the feeble minded who have developed no anti-social tendencies. Every child brought before the Children's Court should be referred to the State Board of Control for mental examination.

7. To the end that the life history of all feeble minded be at all times available, for the sake of the schools, the courts, and the authorities of the State, a bureau should be established at once for the permanent records of all

the feeble minded from birth to death who come within the jurisdiction of the State. Until such time as the proposed Board of Control is organized and provided with necessary facilities the Bureau of Records of the City or State Department of Health should be the official depository of such information as may be obtained.

8. We believe that there is a need for the so-called ungraded classes of the public schools. Our criticism of such work as is now done for the feeble minded by the Department of Education of New York City is that the examinations and tests and selection of children suitable for education have not been under adequate medical direction, and that the equipment and organization are insufficient. Furthermore, we find no provision for the morally defective who are found at present in the regular classes of the public schools.

9. We believe that although a department of charities is not a suitable agency of government to take upon itself the permanent control of the great problems of the feeble minded, nevertheless, under existing conditions and until such time as a Board of Control may be established, there is a legitimate field for the present activities of the Department of Charities.

Any thoroughgoing organization for the care of the feeble minded and protection of the State from their incapacity, criminal tendencies, and their baneful effect upon their progeny should contemplate: (1) State control cooperating with existing local or municipal agencies. (2) A permanent bureau of life records with compulsory notification and registration. (3) Self-support where possible for the feeble minded. (4) Segregation and detention where necessary. (5) Prevention of the propagation of their kind. (6) An organized and permanent campaign of study and education, for the prevention of the causes which lead to feeble mindedness.

**Need for Proper Hospital Provision for Children.**—The sub-committee on Hospitals held a meeting at which was discussed the matter of meeting by municipal appropriation the urgent need of proper hospital provisions for children. The unanimous opinion of the sub-committee was that it would be inadvisable to build a special hospital for children and that a separate children's service at the general hospitals is much preferable, provided that if possible such a service is constituted as a distinct department with a single head and continuous service.

The scientific session was held under the auspices of the Department of Surgery in Columbia University.

**A Preliminary Morphological Study on Certain Developmental and Pathological Changes Occurring in the Mammary Gland.**—Dr. Hugh Auchincloss presented this communication which he illustrated with lantern slide pictures. He said that to understand the rationale of certain clinical symptoms and pathological processes, it was most important that a few fundamentals concerning development and anatomy should be clearly understood and these it would be the purpose of his paper to discuss. The human breast was a gland derived from the epidermis by a process of epithelial invagination into the corium and subcutaneous tissues. In the opossum it had the appearance of a sweat gland, but in the human being there were features resembling both sebaceous and sweat glands. A normal, inactive human breast showed groups or lobules of small canals, lined by two layers of epithelium. These canals joined to form ducts opening into the nipple. One large nipple represented a complete gland system in itself. Of these systems there were a variable number from approximately fifteen to twenty-three. It was of importance to recognize the character of the stroma and the disposition of the fat bundles. Close to the epithelium was the intralobular stroma showing a loose arrangement of young connective tissue cells and capillaries, in marked contradistinction to the interlobular stroma composed of more mature, longer, white fibrous connective tissue, elastic fibers, and the larger vessels and nerves. An origin and analogy of these structures was evident as one examined a diagrammatic sketch of the more prominent skin structures. The pathogenesis of mammary cysts had been for generations a subject of extensive investigation; there were a great many varieties from a morphological standpoint, and Dr. Auchincloss presented slides to demonstrate certain features that occurred in the earlier stages of cyst development in this disease.

**The Possibilities of Preserving the Integrity of Potential Body Cavities by the Use of a Foreign Body to Prevent Adhesions.**—Dr. Frederick Prime, Jr., threw on the screen pictures of the work done with the use of foreign bodies in certain cavities to prevent adhesions. They found in cellulin a substance free from irritation and which prevented adhesions. Pictures showed the application of this substance in brain surgery on animals; the part next to the dura mater was attached by fibrous tissue, while the part next to the brain substance remained free of adhesions for long periods of time after the operation.

Dr. Charles H. Peck believed that the material described by Dr. Prime should have a large field of usefulness because it was non-irritating and could be left in the tissues for long periods of time without any resulting reaction at all. He believed it to be specially applicable in nerve and tendon suturing; here it certainly had a distinct field. In the surgery of joints also there was a promising field; at least from the experimental standpoint. It seemed to him that this was the best material for this purpose both because it could be sterilized so readily and because of the ease with which it was handled. It certainly had a field in work upon the peritoneum and here it should be given a trial.

**The Adaptation of the Cinematograph in the Study of Tissue Growth.**—Drs. J. E. McWhorter and Frederick Prime, Jr., showed some moving pictures of the chick blastoderm in its various stages of development, and of tissue cultures, particularly the activity of their isolated cells. In the development of this work their object had been twofold: to present to students in their study of tissue growth and the early development of the embryo, a graphic picture of the changes which these tissues underwent; secondly, to reproduce for study such movements as were not readily followed by the eye, as, for example, the rapidly beating embryonic heart, or the movements and division of the slower growing tissue cells. The technique used in the preparation of the chick blastoderm for purposes of photomicrography was described. With this method they had succeeded in keeping alive, and had observed the development of very young chick blastoderms, those of twenty-four-hour incubation, for over thirty-one hours. It was possible to observe the developing heart from before the first beat up to and including the first appearance of the blood cells in the primitive circulation. This formed the first group of pictures shown. The second was one showing the primitive circulation taken from different areas in the area pellucida, and the third showed tissue cultures.

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting, Held January 7, 1913.*

The President, Dr. L. Pierce Clark, in the Chair.

**A Case of Cholesteatoma of the Brain.**—Dr. I. Strauss reported this case and showed the specimen. The patient was a woman, thirty-two years old at the time of her death, who was admitted to the Mt. Sinai Hospital on October 5, 1909. The patient was one of twins; the other was healthy. One brother was mentally deficient. The patient's past history was unimportant. When she married, at the age of 22, her weight was 95 pounds. Menstruation began at 15 and was regular until the birth of her second child, six or seven years ago. She had three children, living and well, the youngest sixteen months old. No miscarriages; never had any skin eruption; no cardiac, pulmonary or gastric disturbances. Her present illness dated back to the birth of her second child, when she began to have menstrual disturbances, having periods every two or three months. There was no pain. During this time she became obese and was steadily growing stouter. She complained of headache, and about five months after the birth of her last child she first showed signs of mental derangement. She lost her memory and talked garrulously and incoherently, and was committed to an asylum in Central Islip, where she remained about nine months. During her stay in the hospital she had pneumonia, from which she recovered without complications. Since her return home her headaches had increased in severity and recurred more frequently. She often vomited small quantities of food; not projectile in character. For the past six months she gnashed her teeth almost continually, stopping only during conversation and mastication. Her eyesight had been gradually growing poorer. Her memory was fair, but she forgot recent happenings and she took very little interest in current events. She complained of pain in the jaws and of some difficulty in chewing and swallowing. She was also subject to earache. She had great thirst, drank considerably and voided copiously. Perspiration was profuse. The bowels were constipated. She had not menstruated in four months. She continued to gain weight, although not as rapidly as formerly. The patient's facial appearance at the time of her admission to Mt. Sinai

Hospital was suggestive of acromegaly. The lips were thick, the upper jaw seemed wider than normal, and her nose was thick and broad. The teeth were regularly placed and ground from the constant gnashing. The hair was coarse and sparse, and there was a considerable growth on her upper lip. The axillary and pubic hair was likewise sparse. Her mentality was dull and sluggish. She was indifferent to her surroundings, and her attention was easily distracted. She was oriented, but her memory was very deficient. The subcutaneous fat was very sensitive. The uterus was small. The blood pressure was 90, and the temperature averaged about 98.3°. There was some atrophy and weakness of the right leg, with diminished reflexes, suggestive of an old anterior poliomyelitis. Glycosuria was present. The fundi were negative, although on account of the restlessness of the patient, neither a satisfactory examination of the visual fields nor an *x*-ray could be made. Dr. Strauss said the diagnosis of pituitary tumor was made, based on the early appearance of Froelich's syndrome, the character of the facies and the symptoms of increased intra-cranial pressure. The unusual feature was the development of a true diabetes. In April, 1910, the patient was transferred to the Montefiore Home, where it was ascertained that she had a positive Wassermann reaction in the blood (negative in the cerebro-spinal fluid), and that there was not much doubt that her husband had been luetic. At this time the right eye showed atrophy of the disc; the left a commencing atrophy, and there appeared to be a bilateral temporal hemianopsia. She remained in a stationary state for some time, when she suddenly became somnolent and developed a marked edema of the face and lips. She came out of this state after a few days and was given an intramuscular injection of salvarsan. The improvement in her mental condition produced by this was very remarkable: she took cognizance of her surroundings, her memory improved, she thanked the physicians for what they had done for her and felt sure she could return home in a short time. The glycosuria gradually disappeared, and she was maintained on an antidiabetic diet. Six months later there again suddenly appeared an extensive edema of both upper eyelids. There were subconjunctival hemorrhages, the pupils were moderately contracted and she became comatose, with stertorous breathing, loss of all reflexes and incontinence; no sugar. A phlebotomy was performed, bicarbonate of soda and diuretin administered, and in two days the edema had disappeared, the patient came out of her coma and was mentally clearer than she had been in six months. During the succeeding three months she was given several injections of salvarsan, together with mercury in different forms. She remained fairly clear mentally and her general condition was good. Sugar was absent for considerable periods of time, and, if present, it was only in small amounts. There was very little headache or dizziness. Early in December, 1911, she became semi-stuporous and slept a good deal. The stuporous condition became more marked, and death occurred on December 21.

At the autopsy, which was confined to the brain, a tumor was found on the under surface of the brain. It presented as a cystic and gelatinous mass, extending from the medulla at the inferior level of the olivary bodies forward as far as the optic chiasma. The main prominence of the tumor presented itself on the left side of the pons, in the interpeduncular space. The tumor compressed the pons, especially on the left side, although also some of the right half of the pons had been destroyed. The destruction of the pons on the left side extended inward to about its width. In this region the tumor was both cystic and solid, the cyst being about 1.5 cm. in diameter. The solid part of the tumor was yellowish in some places and darker in others, where it was of a gelatinous appearance, and there were numerous small, yellow areas scattered throughout the mass in this region, which contained hard, calcareous substance. The third nerves could be seen coming out on either side of the mass. The main body of the tumor occupied the region of the basilar ganglia on the left side. The left lenticular and caudate nuclei were compressed and displaced laterally, and the left interinal capsule was missing in its lower two-thirds. The fornix and septum lucidum were displaced to the right and the optic thalamus appeared to be completely replaced by the tumor. In one portion, the tumor broke through the floor and lateral wall of the left ventricle, and projected as a mass the size of a pea into the ventricular cavity. The tumor extended forward into the frontal lobe almost to the frontal pole on a level with the second frontal convolution. The tumor measured about 5 cm. in its longest diameter, from above downward: its greatest width was 4 cm. It appeared to be encapsulated, the capsule above being a thin bridge of brain tissue one and a half mm. in thickness, which formed the floor of the left ventricle. The hypophysis seemed to be of about normal size, but somewhat flattened. Microscopically, the growth proved to be a cholesteatoma, possibly of embryonal origin.

**A Case for Diagnosis.**—Dr. Foster Kennedy presented a married woman, thirty-five years old, who had enjoyed good health up to about one year ago, when she began to suffer from severe headaches, and six months later there was added to these intense attacks of vertigo, with frequent vomiting. Three weeks ago she first noticed that her left eyelid drooped, and that there was weakness of the left face, which became twisted when she laughed. She now complained of severe headaches, intense dizziness, frequent vomiting, and incomplete paralysis of the left third nerve. Her reflexes were normal. There was no ataxia. Her speech was normal. The Wassermann reaction was negative and an examination of the cerebrospinal fluid gave negative results. There was slight inequality of the pupils, the left being smaller and more sluggish than the right. There was no nystagmus. Dr. Kennedy said this patient had been under his observation for only a short time, and he had made a very tentative diagnosis of pontine tumor.

Dr. I. Abrahamson said the case shown by Dr. Kennedy recalled to his mind that of a child that was brought to the clinic with a paralysis of the sixth and seventh nerves on the right side, followed in the course of two weeks by headaches of increasing severity. The symptoms were first regarded of peripheral origin. Subsequently, the child had a convulsion, with hyperesthesia and right-sided paralysis, the symptoms pointing to a pontine tumor. The patient was growing progessively weaker, and a fatal outcome was expected. In another case, which Dr. Abrahamson said he had presented at a previous meeting of the Society, the patient was a woman with a progressive bilateral opthalmoplegia externa. She gave a history of severe headaches, followed by ptosis and weakness of one side of the face. After temporary improvement she developed a similar condition on the opposite side of the face. The headaches were of an intermittent character. In Dr. Kennedy's case, the speaker said he was inclined to believe that there was a neoplasm involving the pons.

Dr. William M. Leszynsky suggested that the symptoms were due probably to a syphilitic basal meningitis.

**A Case of Extracerebellar Tumor; Operation; Recovery.**—Dr. Foster Kennedy reported the case of a boy, nineteen years old, who was admitted to the N. Y. Neurological Institute on June 12, 1912. The history obtained was that he had always been bright, but not overstudious. He was fond of music and quite an accomplished violinist. His general health had been good. Four years ago he received a severe blow on the head, and at that time it was noticed that his right upper eyelid drooped. When a small boy he told his father that he could not see through a pair of opera glasses with both eyes, and at a subsequent examination, made by an oculist, it was said that the sight of his right eye was practically gone. There was no history of headaches nor convulsions during infancy or childhood. The boy's present illness dated back to March 18, 1912, when he attended a party and ate a good deal. On the following day he complained of persistent headache which at first was in the left temporofrontal region, later extending to the left side of the face and neck to the mid-line. The headache had persisted more or less constantly, but there were intervals during which he was free from it. Between the onset of his illness and April 1st he had vomited once. Early in May it was noticed that he could not play the violin well, due to inability to grasp with the left hand. A few days later it was noticed that he wobbled in walking: this symptom became more pronounced, and the father stated that the patient fell to the left. About two weeks later he had a severe vomiting spell, with much pain in the head. Since then he had vomited only four times, always late at night. When Dr. Kennedy first saw the patient, on June 10, 1912, an examination of the eyes showed a choroiditis, with heaping of retinal pigment in the right eye, and the pupil was more sluggish than that of the left. There was occasional slight nystagmus to the left; never to the right. There was slight infra-nuclear weakness of the left face, with deviation of the jaw to the same side. There was ataxia of the left arm and leg, with a tendency to fall to the left side. No sensory changes were found. On June 14, the patient complained of severe headache in the frontal and occipital regions, but more frontal than occipital, and there was marked

projectile vomiting. There was now gross coarse nystagmus on looking to the left. There was no impairment of smell. The eyes now showed definite blurring of the discs, with small striate hemorrhages. The pulse was slow. The left knee jerk was slightly more active than the right. On June 5, 1912, the patient was operated on by Dr. Charles A. Elsberg, the idea being to relieve intracranial pressure. Upon making an opening over the left occipital region, there was enormous pressure, and the left cerebellar lobe immediately protruded to such an extent that it was almost strangulated before the dura could be incised. The left cerebellar lobe was then seen to be apparently the seat of an infiltrating tumor, apparently a glioma, extending from before backwards. Some of this tissue was removed and the wound was closed. The patient made an uneventful recovery from the operation, with the exception of a slight rise in temperature, with occasional vomiting, on the fourth day. On June 25, his temperature had again fallen to normal; there was no vomiting or pain. On July 2, the ataxia was less marked and there was a general improvement in the patient's condition. There was no pain nor vomiting, and he was able to sit up voluntarily without effort nor dizziness. He left the hospital on July 6. The patient's present condition was entirely satisfactory. He considered himself practically well, and had resumed his violin practice.

Microscopic report. No gliomatous tissue was found in the specimen, so the good result in this case was entirely produced by a simple decompression, the growth being still in front of the exposed cerebellar lobe.

Dr. L. Pierce Clark said that in dealing with slow growing tumors of the cerebellum, especially in early life, it was difficult to say just what was going on either in the tumor or cerebellum itself by the symptoms presenting, as the frontal lobes of both sides were closely connected with both cerebellar lobes and had reciprocating functions. Though the cerebellum made little recovery after tumor removal, it was quite possible for the frontal brain to take up cerebellar functions of equilibration and defective muscle tonus and regulate the same through the cerebro-cerebellar pontine tracts.

**A Case of Acoustic Neuroma.**—Dr. I. Abrahamson presented a girl, nineteen years old, a native of Bohemia and a domestic by occupation, who had suffered from headaches and tinnitus for over two years. Subsequently she complained of vomiting and vertigo and of increased noises in the left ear, with diminution of hearing. For four months she had complained of visual disturbances, with gradual loss of sight. The gait was unsteady, with staggering toward the left side. The vision of the left eye was less than that of the right. For the past two months there had been amenorrhea. Examination of the eyes showed double choked disk, with consecutive atrophy, most marked on the left side. It was impossible to map out the fields, owing to poor vision, the patient being scarcely able to count fingers. The ocular movements showed coarse nystagmus to the extreme left; less marked to the right. The pupils were large, some reaction to light was present. Smell was impaired; taste was normal. There was corneal hyperthesia. The right face was flattened; there was spasm of the left face. Hearing was very defective on the left side; that on the right side was somewhat diminished. The head was held in the left cerebellar attitude; there was a cerebellar gait, with a tendency to fall mainly to the left. There was no hypotonus; no ataxia. There was some weakness on the right side. Sensation was intact and the sphincters normal. The deep reflexes were slightly increased; no Babinski. The Wassermann reaction was negative. Dr. Abrahamson said the symptoms in this case were typical of an acoustic neuroma. The absence of facial paralysis on the left side was not unusual.

**Officers.**—The following officers were elected for the ensuing year: *President*, Dr. Smith Ely Jelliffe; *Vice-President*, Dr. E. W. Scripture; *Corresponding Secretary*, Dr. J. Ramsay Hunt; *Recording Secretary and Treasurer*, Dr. C. E. Atwood.

---

**Revocation of Osteopathic License Obtained by Fraud.**—When an applicant has been registered under the Pennsylvania act of 1909, P. L. 46, as a practitioner of osteopathy, and the board of examiners subsequently learns that the registration was obtained by means of a diploma fraudulently issued and obtained by him, the board's course is said to be to afford the applicant a hearing, and if satisfied that the license was obtained by fraud to take formal action to revoke the license. The applicant's false affidavit as to his attendance at lectures does not make him liable to a conviction of perjury.—Simmons' Case, 38 Pennsylvania Co. Ct., 195.

## CLINICS, DEPARTMENT OF PUBLIC CHARITIES

Calendar, March, 1913

| | | | |
|---|---|---|---|
| **MONDAYS** | | | |
| *City Hospital* | Surgery | Dr. Dawbarn | 2:30 P.M. |
| | Dermatology | Dr. Fordyce | 3:00 P.M. |
| *Cumberland Street Hospital* (Brooklyn) | Surgery | Dr. Walmsey | 3:00 P.M. |
| | Laryngology and Rhinology | Dr. Stewart | 4:00 P.M. |
| | Oral Surgery | Dr. B. Shea | 4:30 P.M. |
| **TUESDAYS** | | | |
| *City Hospital* | Ophthalmology | Dr. Gilfillan | 2:00 P.M. |
| *Neurological Hospital* | Neurology | Dr. Byrne | 9:00 A.M. |
| *New York City Children's Hospitals*, Randall's Is. | Orthopedics | Dr. Ogilvy | 10:00 A.M. |
| *Cumberland Street Hospital* (Brooklyn) | Ophthalmology and Otology | Dr. Lloyd | 3:00 P.M. |
| | Surgery | Dr. Iler | 3:00 P.M. |
| *Kings County Hospital* (Brooklyn) | Obstetrics | Dr. Commiskey | 10:00 A.M. |
| | Genitourinary Surgery | Drs. Norton and Fraser | 2:00 P.M. |
| | Surgery | Dr. Bristow | 2:00 P.M. |
| *Coney Island Hospital* | Surgery | Drs. Fiske and Bogart | 10:30 A.M. |
| | Surgery | Drs. Murphy and Lack | 10:30 A.M. |
| | Medicine | Drs. Hall and Nash | 3:30 P.M. |
| | Medicine | Drs. Hegeman and Byington | 3:30 P.M. |
| **WEDNESDAYS** | | | |
| *City Hospital* | Surgery | Dr. Dawbarn | 9:00 A.M. |
| | Medicine | Dr. Quimby | 1:30 P.M. |
| | Genitourinary Surgery | Dr. Greene | 2:00 P.M. |
| | Obstetrics | Dr. Dorman | 2:30 P.M. |
| *Metropolitan Hospital* | Surgery | Drs. Bogg and Honan | 2:30 P.M. |

| *Kings County Hospital* | Obstetrics | Dr. Commiskey | 10:00 A.M. |
| | Surgery | Dr. Bristow | 2:00 P.M. |
| | Pediatrics | Dr. Little | 3:00 P.M. |
| | Medicine | Dr. Stivers | 3:30 P.M. |

ALL REGISTERED PHYSICIANS, VISITING AND RESIDENT, AND MEDICAL STUDENTS ARE CORDIALLY INVITED TO ATTEND THESE CLINICS.

Cards of Admission, valid until October 1st, 1913, may be obtained at the *Academy of Medicine*, 17 *West 43rd St., Manhattan*, and at the *Medical Society of the County of Kings*, 1313 *Bedford Avenue, Brooklyn*, as well as from the secretaries of the several medical colleges.

## Therapeutic Hints.

**The Treatment of Bronchitis in Infancy and Childhood.**—In his recently published work, G. A. Sutherland states that the patient should be confined to bed during the acute pyrexial stage, and should be given a restricted fluid diet. Warm demulcent drinks may be given freely. If the cough is dry and irritating steam inhalations may give great relief. If the secretion of mucus is free or over-abundant, the use of steam is contraindicated. The steaming should not be continuous, but should be employed for fifteen minutes at a time every hour or two. If there is dyspnea resulting from spasm of the bronchial tubes the application of hot fomentations to the back and front of the chest will often give relief. A dram of turpentine may be added to the fomentation. If plain fomentations are used they may be applied continuously for an hour and then intermitted. In many mild cases of bronchitis it will suffice to apply to the chest twice a day a stimulating liniment such as the following:

℞ Liniment. terebin. acet. (N. F.), ʒiii.
Liniment. belladon., ʒj.
Olei dulcis, ʒii.

At the ouset of the attack the bowels should be freely opened. Three grains of rhubarb powder and two grains each of gray powder and carbonate of magnesium may be given at night, and followed by a dram of sulphate of sodium or magnesium in the morning. A simple febrifuge mixture such as the following may be ordered:

℞ Liq. ammon. acet., ♏xv.
Potass. citrat., grs. v.
Tinct. aurantii, ♏v.
Aq. camphor., ad ʒj.

As regards cough mixtures the author points out that most of these tend to upset the child's digestion. Prescriptions are common in which one finds drugs to increase expectoration, or to diminish expectoration, or to do both at the same time. In the early stage of bronchitis, when secretion is defective, and a harsh irritating cough may be associated with dry catarrh of the tubes, potassium iodide (gr. ii and carbonate of ammonium (gr. ss—j) may be added to the above mixture or given separately as long as necessary. Only when secretion is over-abundant is it necessary to interfere in order to diminish it. This may be effected by the following:

℞ Tinct. belladon., ♏iv.
Ac. nitrohydrochlor dil., ♏iij.
Glycerin, ♏x.
Inf. gent. co., ad ʒj.
M. et Sig. ʒj every four or six hours.

When the patient is troubled with a persistent cough one should examine the nasopharynx and throat for signs of irritation which may be relieved by a nasal lotion or a simple throat lozenge. If the night's rest is disturbed five to ten drops of paregoric may be given occasionally for its relief. If special sedatives seem called for, a convenient mode of administration to children is the use of pastilles, which may contain one-fiftieth of a grain of morphine or codeine. In the convalescent stage the patient should have a sufficient amount of animal fat. A combination of cod liver oil and hypophosphites gives good results in restoring a healthy condition of the bronchial tubes.—"The Treatment of Disease in Children."

## Miscellany.

**Reports of Cures.**—C. B. Lockwood tells the story of the philosopher who was taken to see the temple of Neptune. Around the walls were the pictures of those who had made dangerous voyages in ships, like those of St. Paul, and naturally they were glad whenever they touched land again, and their votive offerings were hung in the temple of Neptune. The philosopher was asked to gaze on the pictures and acknowledge the goodness of the sea-god, the preserver of the givers. But he said, "Now show me the pictures of those who went to sea and did not come back?" So when wonderful cures are told, ask about those who were not cured.—*The Clinical Journal.*

**Danger to the Motorist in Weak Bridges.**—Among the formalities of transcontinental truck touring perhaps none is more edifying than the very necessary one of inspecting and reinforcing wayside bridges. The inadequacy of the modern highway to modern needs is something to be endured, but the inadequacy of the average county commissioner's ideas with regard to bridge construction is more serious. Rotten wooden bridges are a menace that lies in wait for every motorist traveling an unknown way, but it required the advent of the truck to make their ridiculous antiquity perfectly apparent.—*Automobile Topics.*

**Royal Dentists**—The need for some wholesome relaxation is felt by high and low alike; and even kings have not disdained to occupy their leisure hours in working with their hands like the meanest of their subjects. Louis XV, one of the idlest of men, strove to dissipate his continual boredom by means of a private printing press set up for him in his apartments at Versailles by Quesnay, Madame de Pompadour's favorite doctor; and Louis XVI, his grandson and successor, became in course of time a skilful locksmith. Neither of these monarchs, however, was as versatile in his amusements as the ill-fated hero of Flodden, King James IV of Scotland, who was not only an amateur carpenter and blacksmith, but a dentist to boot. The accounts of his private expenditure, extracts from which are given in Miss Green's "Lives of the Princesses of England," prove that although he indulged his eccentric tastes at the expense of those who surrounded him, James knew how to console his victims for the sufferings they endured at his hands. That the royal dentist's involuntary patients were well paid for their complaisance is shown by the following extract, quoted by Miss Green, though one wonders why the unfortunate Kynnard was less generously treated than the anonymous "fellow" who preceded him:

| | £ | s. | d. |
|---|---|---|---|
| Paid for a psalter, three compasses, a hammer, a turcase to take out teeth, and two pair of beads, to the King..... | 0 | 7 | 8 |
| *Item*, to ane fellow because the King pullit furht his tooth..... | 0 | 14 | 0 |
| *Item*, to Kynnard, the barber, for twa teith drawin furht of his hed be the King..... | 0 | 14 | 0 |

This recalls Major Drury's amusing story of the savage potentate who, like the Scottish king, was afflicted with "a mania for experimental surgery," and cheerfully sacrificed the teeth of his unhappy courtiers.—*British Medical Journal,* February 8, 1913.

### THE SCOPE OF DISEASE.

By R. G. ECCLES, M.D.,

BROOKLYN, NEW YORK.

We are beginning to learn that the scope of human maladies is but a narrow fringe along the borderline of a vast empire of disease. We are, likewise, discovering that if we really wish to solve properly some of our most important problems of medical and sanitary science we must extend our knowledge far into the unexplored regions of this empire. This needed extension is greatly hindered by a number of inherited theories that are founded upon the over-narrow range of the facts known in pre-scientific times. The confident acceptance of these theories as an adequate expression of truth extinguishes all desire for greater enlightenment, while the intensity of modern specialization helps to hinder the widening of each individual's range of mental vision. Thus these theories are perpetuated and progress is retarded. This unsatisfactory state of affairs is likely to continue until a larger number of educated laymen and physicians come to know more of the principles being discovered in departments of study cognate to their own. Most of us know too little of what is being done in zoopathology, phytopathology, protozoology, entomology, bacteriology, and biochemistry. A technical knowledge of all of these, by any one individual, is impossible. Sufficient knowledge so as to know where and how they touch our own field of work is both possible and desirable. If more of this kind of information appeared in medical literature, so as to show physicians the real relative dimensions of their own territory, it would help to correct this evil. Like an Andorean the average medical man almost comes to feel that his mountain fastness of tranquil isolation is all that is worth knowing in pathogenic science. As long as he is unable to realize that the scope of medical science outside of his small sphere is vastly greater than it is within, he is not likely to feel much tender sympathy for, nor willing to offer much assistance, to the scientific pioneers who are exploring what to him is a dark *terra incognita*. He has yet to learn that there are problems of supreme importance that are common to plant as well as to human diseases and that can only be mastered by a study of both. The symbiosis of parasites, their co-hosts, and bridging-hosts, their dependence and interdependence upon one another, with all that these imply in relation to the origin and spread of epidemics, can be mastered only when we have a full biological comparative pathology and when our profession is willing to encourage such study with its plaudits. As well might we try to study the conditions of a deluge, when knowing nothing of the great streams and mountain torrents that lie above us on the watershed, as to try to determine the origin of new diseases and of vast, new pandemics before knowing anything about such relationships. If we long for a solution of the problems of parasitic virulence and of cell-resistance to such virulence we should come in touch with those who are seeking, like ourselves, these principles as displayed in plant and animal pathology. If we take no interest in their work how can we hope to have them take much interest in ours. If we desire to know exactly how much reliance we should place on plant and animal experiments, when applied to the solution of human disease-problems, we must learn the bearings of the law of continuity upon such problems. If this great law is as dominant over the problems of disease as it has been found to be over those of every successfully developed inductive science until we have mentally compassed a clear understanding of the real scope of disease, we must remain blind to its bearings and lost to its mnemonic value. If, as evolution clearly implies, the protein molecules of our tissues are, phylogenetically, related to each other, through the law of continuity, as morphological structures are known to be, then biochemistry ought to be able to reveal this sort of continuity in the digestion-resisting surface-coverings of men and beasts, birds and fishes, insects and crustaceans, trees and shrubs, herbs and grasses. Until medical men show more interest in this subject than they do to-day biochemists are bound to neglect it in spite of the fact that such a line of study, from our viewpoint, gives promise of being able to supply us with the exact meaning of inborn immunity and constitutional superiority. No interest, however, can be aroused in this until there is first an interest established in the broad and deep aspects of parasitism. We cannot become interested in problems that to us are non-existent. There are many more fundamental problems of pathology, the solution of which cannot be reached until the medical profession takes more interest in the broader aspects of infection. Some of our most cherished beliefs may yet have to give way before the advance of the newer knowledge simply because they are deductions from data collected from a too narrow field or they are inferences from our ancient heritage of faith. Our slowness in keeping pace with the progress of cognate science is attracting far more attention among educated laymen than most of us are aware of. It is not long since the following statement appeared in no less a journal than *Science*, and by no less a person than a leading paleontologist of the State of New York, whose name is starred in the directory of American Men of Science. He said: "In the average American community there is among practitioners of medicine and surgery an indifference to or failure to grasp the purport of pure biologic research, so complete and dense as to be appalling,

the more as it lies in a quarter where one might most reasonably hope for support and sympathetic concern. Compared with the intelligent manufacturer, the wholesale merchant, the banker, the stock broker, the modern farmer, the average physician or surgeon carries toward the ideals of our science and of geologic science as well so far as the results involved are not strictly commercial, an air of indifference that partakes of the supercilious."[1] Think of such a statement being sent into the homes of the best educated families of our nation. Think of its remaining unchallenged and uncontradicted—and why? Think of the effect it must have had in undermining the faith which intelligent laymen have in our profession. When first read by the writer of this paper it produced a feeling akin to heart-sickness. Why do we not at once awaken to a consciousness of so unpleasant a situation? Why should not our medical journals devote some space to the presenting of subjects for thought that will encourage a wider study of the newer biology than that which at present obtains? The old, old story of the histories of clinical cases and of pathological specimens, with not a suggestion of living science, is becoming very monotonous to those familiar with better things. It is constantly being repeated, from generation to generation, with little or no variation, yet associated with some sort of vague idea that this sort of thing constitutes science. Case is piled on case, mountains high, with never a protest against its being so greatly overdone. In and around, through and through, every such case and every such specimen run the silken threads of deeply significant principles which careful study could discover and bind into an integral whole. Why do those who present such cases and specimens fail to see these radiating and anastomosing principles? Why do they refuse to breathe into them the breath of living truth? Each such specimen may be but a fragment from a corpse, but there is in this no valid reason for transfixing their facts into excellent specimens of literary mummies. Yet this is about what many of the members of our profession have been doing, and are likely to continue doing indefinitely, unless they awaken to a realization of the elementary biological truth that the scope of human pathology is but a fraction of animal pathology, to say nothing of the still greater mass of plant pathology. No theoretical attempt at explanation which fails to include the latter can properly explain the former. Only those who have made excursions into the wider fields have been able to add anything worth recording to our steps of substantial progress.

We have been hearing a great deal lately about disease "carriers," and we are quite likely to hear very much more concerning them in the no distant future. To learn that apparently healthy people can go around breeding and scattering diseases among others, while at the same time such diseases have no evident ill effects upon themselves, is a strange yet serious state of affairs. It was from zoopathology that our first knowledge of this remarkable phenomenon came. Several years later it was proven to be a common law of disease among plants as well as among animals and human beings. This standing evidence of what Goethe called "the linked purpose of the whole" can scarcely be looked upon as a benevolent "purpose," from the ordinary viewpoint that disease is an evil, unqualifiedly. It is evidence of a sameness which runs through and through disease wherever found. Theobald Smith first recognized the living "carrier" in those cattle from our Southern States that convey the *Pirosoma bigeminum* across Mason and Dixon's line. Dr. D. E. Salmon gave us the following graphic description of how this germ of Texas fever, through the aid of a tick, does its work. He says: "The cattle which spread the disease are, themselves, apparently in good health, while the cattle that become sick do not themselves disseminate the contagion. Again, susceptible cattle might be mingled with impunity with cattle from the infected district, providing this mingling occurred immediately after their arrival, and did not continue longer than two or three weeks; while, on the other hand, susceptible cattle that later in the season trespassed for even a few minutes on the pastures where the infectious cattle had been would contract a most violent form of the malady. * * * Texas fever is caused by a microscopic parasite, which lives within the red globules of the blood. The cattle in the infected district carry this parasite permanently, and are so nearly immune to its effects that they remain in good health, nothwithstanding its presence in their blood. Not so, however, with cattle which never before have encountered it. With such animals it destroys the red corpuscles and reduces them to one-third or one-fourth the normal number. An intense fever is produced, and the creatures rapidly waste away and die after a sickness of one or two weeks."[2] The East Coast fever of Africa duplicates in most particulars Texas fever. The African disease is caused by *Piroplasma parvum* (Theiler), a very closely related parasite, which likewise lives in the interior of the red blood cells of its host. The cattle of the East Coast are immune to its attacks but are the "carriers" of the disease germs. Nonimmune cattle, that are unfortunate enough to be driven through the East Coast region, are certain to be attacked, and a leading authority has asserted that only about five out of one hundred of those animals that catch the disease survive. In one epidemic, due to infected animals being taken to the Transvaal, 15,000 cattle died. In trypanosomiasis we have another repetition of this same condition. The authority just referred to tells us that notwithstanding the fact that there may be no sick animals in the fly country of Africa, "no horses, cattle, nor dogs can venture, even for a day, into the so-called 'fly country.'" Stating his experience he says: "There were no sick horses or cattle in the 'fly country.' Investigation brought to light the curious fact that most of the wild animals—the buffalo, the koodoo, the wildebeeste—carried the trypanosomes in small numbers in their blood, and it was from them that the fly obtained the parasite. The wild animals act as a reservoir of the disease. The trypanosome seems to live in the blood of the wild animals without doing them any harm, just as the rat trypanosome lives in the blood of healthy rats; but when introduced into the blood of such domestic animals as the horse, the dog, or the ox it gives rise to a rapidly fatal disease."[3]

The almost complete destruction of the wine industry of France by the introduction of downy mildew and phylloxera, chronic parasites of our wild American grapes, is another vivid example of what the disease "carriers" can accomplish even in the plant world. Our inability to grow European gooseberries in this country, much as

those of us who know the size, flavor, and sweetness of such berries regret the matter, is due to the fact that the gooseberry mildew of our native wild gooseberries makes such growth almost impossible in this country. Recently some wild American plants were carried over to Europe and the mildew from these has been so destructive that growers are in great fear of the results. They are endeavoring to exterminate the disease by killing off every infected gooseberry plant that can be discovered. Add to these the hollyhock rust from Chili, that threatens the extermination of European and American hollyhocks; the coffee fungus *(Hemileia vastatrix)* that has actually destroyed the coffee industry of Ceylon, and is now threatening the coffee plantations of other countries; the blister blight of tea that has completely exterminated hundreds of acres of tea plants; the asparagus fungus *(Puccinia asparagi)* that has ruined many acres of asparagus in California, New Jersey, Delaware, and Long Island; and the chestnut fungus *(Diaporthe parasitica)* that is now browning our forests with the dead trunks of chestnut trees;[4] and we have a formidable list of disease destruction that is probably all due to wild plant "carriers." Once started among cultivated plants of the same or related genera and the damage done reaches into many millions of dollars.

Almost every kind of crop grown on our farms is now regularly subject to immense annual loss because of diseases, the origin of which is at present untraceable, but due, probably, at first to wild plant parasites. "There is little doubt," says Professor Orton, "that the average annual loss from oat smut is more than $6,500,000; from loose smut of wheat, $3,000,000, and from bunt, or stinking smut of wheat, more than $11,000,000. Barley loose smut annually diminishes the value of barley more than $2,000,000, a careful estimate of the loss in one state last year placing it at 7 per cent. of the yield. * * *. The combined effect of the several leaf blights of the potato is to diminish the yields of this crop over $36,000,000 each year. The losses of the cereal rusts and from the numerous minor troubles of farm crops, concerning which accurate data are difficult to secure, amount to hundreds of millions of dollars."[5] Professor Massee, in discussing the same phase of the subject, tells us that: "It is well within the mark to state that the annual loss throughout the world, due to injury caused to cultivated plants by parasitic fungi, exceeds 150,000,000 pounds sterling ($750,000,000). Probably double this amount would be nearer the truth. * * *. According to the Prussian Statistics Bureau, the losses in Prussia during the year 1891 from grain rust attacking wheat, oats, and rye, amounted to 20,628,147 pounds sterling" ($103,140,735).[6] For the purpose of trying to arrest this tremendous financial loss experiment stations have been started in this and other countries. They aim at discovering the best way of exterminating these diseases. Direct attacks upon the germs have proven futile and every effort at cure has given sorry results. Within a few years a new method has been adopted. Professor Bolley of the North Dakota Experiment Station is one of its most active promoters. Instead of attempting to hinder the growth of the parasites he aids them as best he can and then leaves the results to the survival of the fittest in the intense struggle he has started. "We place the plants we wish to test," he says, "under all of the disease conditions of the soil, air, and water that we can help nature produce, then save the seeds from those plants for future trial under similar conditions year after year." He adds: "This is a new method in experimental work and has given astonishing results. * * *. We now know that we are on the right track to procure resistant and immune varieties."[7] Professor Orton, another plant pathologist, tells us that by imitating nature in this drastic way there have been produced "(*a*) wilt-resistant sea island cotton, (*b*) wilt-resistant upland cotton, (*c*) wilt-resistant cow peas, (*d*) wilt-resistant watermelons, (*e*) blight and scab-resistant potatoes, (*f*) anthracnose resistant clover, (*g*) leaf blight-resistant cantaloupe, (*h*) rust-resistant wheat, and (*i*) wilt-resistant flax."[8] This is certainly a most excellent showing for the few years during which the method has been on trial. It looks as if we are destined to soon secure, by this method, sufficiently hardy crops to practically be able to defy the majority of well-known plant diseases. The killing off of the unfit leaves only the resisting fit to propagate their kind. The susceptible disappear from the earth. This is why it happens, as stated by Professor Minchin, that "when a race of hosts has long been associated with a race of parasites the hosts gradually acquire constitutional powers of resistance to the parasite, which the hosts do not possess when first brought into relations with the parasite." This is why he is further able to state that "a new parasite will generally be a dangerous one."[9] Gradually, but surely, the susceptible are eliminated and the non-susceptible take their places. The new parasite finds favorable soil on which to grow. The old one meets a resistant tissue that it cannot overcome. Thus it happens "that an infection gradually loses its gravity in the course of centuries, or acquires an unusual malignancy when invading a population until then spared," as says Roger. He then adds: "Nothing is more interesting or instructive in this connection than the epidemics of measles of the Faroe Islands. The disease was imported there in 1846. Of the 7,782 inhabitants, 6,000 were attacked, only the old being spared. In 1875 the same disease invaded the Fiji Islands and caused the death of 40,000 persons out of a population of 150,000."[10] The spread of smallpox among susceptible races tells the same tale. "When taken to the West Indies, in 1507," says Dr. G. Archdall Reid, "whole tribes were exterminated. A few years later it quite depopulated Santo Domingo. In Mexico it destroyed three and a half millions of people. Prescott describes this first great epidemic as 'sweeping over the land like fire over the prairies, smiting down prince and peasant, and leaving its path strewn with the dead bodies of the natives, who perished in heaps like cattle striken with murrain.'"[11] This prairie fire illustration is apt. Europe and America have seen the same law made manifest in pandemics of plague, cholera, and influenza. Gradually they died out as susceptible victims became less numerous, but only to reappear again when acquired immunity ceased to protect those that were saved by its power. Like the new growth of grass on the prairie these supplied new fuel for the fire. After successive reappearances, few but the resisting fit were left and in this way a balanced state of neutrality became established. Where the parasites invade territory in which environmental conditions of temperature and moisture

interfere with their multiplication, they die out before such a survival of fit hosts has become complete. In their original homes they continue being multiplied by carriers and as circumstances permit they spread forth again to renew their mischief. When the balanced state is complete the host is rarely injured greatly by them, unless vitality is lowered or cuts and bruises permit them to reach imperfectly protected cells. This law of adaptiveness, of parasite and host toward each other, leads to the conclusion that the parasites of our acute diseases are such as can still find among us tissue food for which they have to fight. The work of selection is incomplete, notwithstanding the fact that it may have been going on for hundreds or thousands of years. Travelers, commercial men, crusaders, and missionaries of various kinds, have, doubtlessly, been the original carriers that brought them into civilized countries from many native races. What new type they may introduce in future no man can tell. "With growing intercourse," says Theobald Smith, "each original center of population, immunized through centuries and perhaps thousands of years to its own few diseases, would be brought in contact with some fatal plant of another portion of the globe and be partly swept away by it."[12] Only races which have endured the ordeal of an infective disease can ever hope to escape its malignancy on introduction to them. Isolation from it is but a preparation for its most serious manifestation when it does appear. This seems to be the reason why savage races suffer so much worse than we do from the various infections. "The deplorable condition of savages," says the Editor of American Medicine, "must be remembered when we are inclined to wail over our woes. The old idea that primitive man living next to nature was healthy and strong is false. He is now known to be 'a nest of parasites within and without.'"[13] Their resisting power, toward the bulk of our infections, is not at all comparable with ours. While civilized races are rapidly increasing in numbers all over the earth, savage and barbarous nations are as rapidly disappearing before the scourge of disease. Our race resistance grows as each new scourage appears, and our ever-increasing fitness has enabled us to defy all of the relatively new diseases which are at present known. With the parasites of chronic diseases the case seems different.

Every animal and every plant under the sun appears to be compelled to sustain its full share of these balanced scourges. To turn to the right or to the left of any of the conditions which hold them in check is to invoke suffering and often death. Like the sword of Damocles, they ever threaten, and less than the thickness of a hair lies between the best of us and their malignancy. We act as constant "carriers" of these potential enemies. The surfaces of our skins swarm with them. Our intestinal tracks are literally loaded with them. The air we breathe carries them. At any moment a cut, an abrasion, a chill, an indiscretion of any one of many kinds, will sever the thread that holds back death. The discovery of their horrible slaughter, in the past period of human ignorance, brought honor and praise to Ambrose Paré, to Semelweiss, to Oliver Wendell Holmes, and to Lord Lister. Prof. Robert T. Morris has told us that the colon bacillus group—one of the balanced groups to which reference has here been made—is among the most active malefactors of all bacteria in its relation to the sufferings of man. No human intestine is free from them and it is not at all unlikely that almost every terrestrial vertebrate contains them in some of their strains. Dr. Morris has pointed out how malignant they can become in many surgical diseases. The numerous cases of infection of the appendix, of the pylorus, of the duodenum, of the bladder, of the urethra, of the vagina, etc., attest what they may become. He states that "the colon bacillus ranks along with the tubercle bacillus as an agent for preventing overpopulation and regulating the character of population by means of poison," and, he adds, "that this might have been given special attention by Darwin and Malthus had they been in possession of our present data."[14] It is not improbable that the Gaertner and typhoid subgroups of the larger colon bacillus group may be swaps that have been made in the no remote past, thus establishing a higher degree of virulence corresponding to their newness to us. Our streptococci and staphylococci appear to have been man's steady companions for ages. The parasites of pneumonia, meningitis, rheumatism, and gonorrhea are close kin to the streptococci. The diplococcus of gonorrhea cannot live in any other animal than man. Inasmuch as it dies speedily in every other animal than man it must have originated as a species within man. Its known relationship to the diplococci of meningitis, rheumatism, and pneumonia indicates great antiquity, for all of these, within man. As eliminators of excessive population they can all be safely placed along with Dr. Morris' colon group. As destroyers of ova and spermatoza they take the lead. Inasmuch as the destruction of a single ovum, or of a single spermatozan, can advance natural selection as far as the destruction of a single individual, these are millions of times more efficient as selectors than diseases that occur before puberty or in senility. Here we get a hint of the, so far, lost sight of fact that chronic diseases may be immensely more efficient agents of natural selection than acute ones. In the early history of geology the catastrophists were in the lead, but sober second thought left them very much in the rear when evolutionists appeared. It can, the author believes, be safely predicted that the biological catastrophists are going to meet a somewhat similar fate. That there is individual selection is undeniable, but that this method of selection is the chief one can hardly much longer be generally accepted. Soma selection can occur only through germ plasm selection and, hence, anything that strikes directly at the germ plasm as a selector must, necessarily, far exceed in its power that which acts by destruction of individuals. Chronic parasites are the ones that must be looked to as the most efficient agents of natural selection, and in every species, every genus, every order, every phylum, every kingdom of biological nature so far studied, the "old," balanced parasites are found as constant companions, we see that the best possible conditions for germ plasm selection exist everywhere. The consensus of the competent, in every department of biology, fortifies this view, each for his own department.

The presence of disease producing parasites in every nook and corner of living nature is seldom appreciated as it should be. Let us see what a few leading thinkers who have acquired a knowledge of this have to say about it. Huxley tells us that "insects are wonderfully liable to the ravages

of contagious and infectious diseases."[15] Hektoen says that "disease is the common lot of all forms of life—high as well as low, animal as well as vegetable."[16] Loeb tells us that "most higher animals, at least, die by bacterial infection."[17] Metchnikoff asserts that "diseases in general and infective diseases in particular were developed on the earth at a very remote epoch. Far from being peculiar to man, animals, and the higher plants, they attack inferior forms and are widely distributed among unicellular organisms, infusoria, and algæ."[18] J. B. Smith tells us that "parasitism is universal throughout the insect world, modified in many ways. Nothing is exempt, neither the lowest insects nor the highest vertebrates."[19] Minchin declares that "there is perhaps no species of annelid, mollusc, arthropod, or vertebrate which is not liable to become the host of some kind of sporozoan parasite."[20] Calkins states that "it is not too sweeping a generalization to state that every living thing, large enough to contain another living thing, is subject to invasion by parasites. The protozoa, themselves single cells, often play the part of host to smaller protozoan cells, and parasites often infect even the nucleus of ameba, paramecium, vorticella, and other types."[21] Professor Farlow assures us that "the reason for supposing that the species of fungi are more numerous than those of Phænogams (flowering plants) is founded on the fact that in countries whose fungal flora has been most thoroughly studied we find few species of Phænogams which are not already known to be attacked by some special parasite, while the majority of species serve as hosts for a considerable number of species of fungi."[22] Inasmuch as the Phænogams constitute the part of the vegetable world best known to nonbotanists, and looked upon by them as almost the whole vegetable world, and inasmuch as most of these that had been studied contained many parasites to each single kind of plant, it certainly appears as if the plant world had to carry its share of such pests. Calkins, in another place than that already quoted from him, says that "from the wide distribution of the intercellular parasites it is quite possible that no animal is entirely free from protozoa of some kind."[23] As a wide reader of evolutionary literature, Lord Chief Justice Fletcher-Moulton has concluded that "Life is one ceaseless war against these enemies, and the periods of our too transient successes are known as health. This condition of constant and deadly strife not only obtains during our own short lives, bust must have equally obtained throughout the long line of development of which we are the result."[24] Prof. F. L. Stevens, as a phytopathologist, tells us that "Countless diseases of wild plants also are now known."[25] The interested reader who wishes to learn the particulars about the multitudes of diseases which attack cultivated plants will find in Massee's text-books of Fungi and of Plant Diseases, in Duggar's Fungous Diseases of Plants, and Orton's list in the Year-Book of the Department of Agriculture for 1906, some very interesting reading upon the subject. Thomson and Geddes, two well-known British naturalists, give us the following clear and impressive word picture of the condition of abject parasitism as it exists, particularly in the ocean. "Fishes may even swarm externally with trematodes and parasitic crustaceans, internally with cysts and intestinal worms without number. A vivid impression of the prevalence of parasitism is afforded by the capture, not infrequent at a channel zoological station or by fisher folk anywhere, of the huge and majestic sunfish, *Orthoagoricus mola;* and by picking off with forceps into museum bottles his crowds of uninvited passengers—the tuft of barnacles upon his back, the biting isipods like enormous fleas upon his skin, the trematodes sucking like leeches upon his eyes; and within to find not only his alimentary canal crammed with worms more than with food, and his liver changed from its natural brown almost into the likeness of a tangle of white worsted, of which each thread is a tape worm. Neither frog nor lizard, serpent nor bird escapes; indeed birds are peculiar sufferers, witness the too common 'gapes' of poultry, a choking of the windpipe by thread worms, and the numerous parasitic worms which Mr. Shiply's labors have discovered in the well-nigh sacred grouse. Of ticks the shepherd is only beginning to know the full dangers, as of fleas upon man himself. Apart from bacterial and protozoan pests, as yet beyond counting, man is debited by the parasitologist with at least sixty species."[26] But man does not, by any means, seem to be alone in having many kinds. Among trees "Cuboni and Mancini enumerate sixty-five species of fungi which occur on the chestnut, and over three hundred species on quercus." We have already mentioned how *Diaporthe parasitica* is fast killing our chestnut trees, and late investigators have been adding new kinds to the credit of the oaks. Pirotti lists one hundred and four species as feeding at the expense of grape vines.[27] In Professor Clark's "Beginnings of Dependent Life," we are told that "Nature is permeated with such degeneration. Few, probably no, members of the whole vast fauna and flora of the earth are free of the bond of supporting others at the cost of their own effort and vitality. From the protozoa and bacteria to man and the oak every greater or less division of nature is riddled with these dependent organisms. * * *. Were we to begin an investigation of the degenerate condition pervading nature * * * there would be but one conclusion of our excursion; it was clearly stated long ago—the whole creation groaneth and travaileth."[28] It is impossible to attempt a general study of parasitology without soon discovering that this statement of Clark's is but an expression of one of the most important truths, from our present viewpoint, which the science of biology has ever revealed. Another writer, Dr. H. Byrd, has, in Bulletin 3 of the Florida Board of Health, expressed this same idea in these words: "More than one-half of all the animal creation are parasites. Almost every animal is a pauper home for parasites—a dive wherein other species of animals feast and hold their ghastly orgies. Nor is this true of the higher animals alone, but it is equally true for high and low. The human species having more than half a hundred parasites can sympathize with the *Paramecium* which although so small it can only be seen with a microscope, is infested with a smaller parasite, the *Sphærophyra.* And more than this, parasites themselves have parasites."[29]

That parasites parasitize each other has been long known. When Leeuwenhoek, early in the eighteenth century, called attention to his discovery that exceedingly minute as are the pupæ of fleas they had still smaller parasites upon them. Jonathan Swift[30] got hold of this report and, in his satirical way, wrote:

"The vermin only tease and pinch
Their foes superior by an inch.
So naturalists observe, a flea
Has smaller fleas that on him prey,
And these have smaller still to bite 'em
And so proceed *ad infinitum:*
Thus every poet in his kind
Is bit by him that comes behind."

This parasitism of parasites is quite common in nature. As an instance, we find that the most common parasites of the plant world—the fungi—have other fungi ever ready to parasitize them. Concerning this Professor Massee states that "Fungi are by no means immune against the attacks of parasites which consist of other species of fungi. This is true of all the families. In the phycomycetes the species of Mucor are especially victimized." [31]

Our cotton crops at present are being greatly damaged by an insect parasite—the boll weevil—which reached this country from Mexico some years ago. It has been estimated that it now causes a loss of over twenty millions of dollars per year to the cotton raisers of the South.[32] For the purpose of trying to lessen this loss our government has put expert entomologists upon the problem of boll weevil control or extermination. The plan being tried is that of finding parasites that will cripple or destroy the boll weevils. One expert, W. Dwight Pierce, has found that some fifty-one species of weevils, now living as parasites on Southern plants, carry other smaller parasites upon themselves.[33] These can be transferred to the boll weevil and they, being new to it, produce an infection that is severe. In Mexico, the original home of the boll weevil, a species of cotton known as "culluche" grows, which has a unique way of circumventing this insect. When this plant was first seen by Collins and Doyle, "weevils were present in large numbers but were doing comparatively little damage. The bolls are protected by proliferation much more completely than in any cotton thus far studied. Hardly a single boll could be found which had not been punctured, but in all the bolls opened we could not find a single live larva. In fact, the proliferation was so complete that the bolls were hardly deformed, although as many as seven or eight eggs had been laid in a single boll. Proliferating tissue had been formed to such an extent that it was forced out through the opening and dried as a coiled mass on the outside of the boll."[34] Unfortunately "culluche" cotton is so inferior in quality that it is of practically no commercial value. It seems, however, as if some one might try Burbank's method of cross-fertilizing upon it. There would seem to be in it a promise of the production of a hybrid having boll weevil resisting qualities combined with good cotton quality. The "culluche" power of regenerating boll tissue, being hereditary, indicates that this, as an adaptation, may be as old as the species. As other species of Mexican cotton have adopted still other though less efficient methods of checking the boll weevil menace these are confirmatory of the suggestion. This raises the question of the possible antiquity of parasitism. These species changes could hardly be a thing of yesterday. Even if they came as mutants it must have taken a long time to exterminate the susceptible strains and leave the unsusceptible masters of the country. How far the boll weevils have changed in the direction of becoming new species has not been investigated.

Parasites change more slowly than do their hosts. One mycologist, E. S. Salmon, has made such an investigation in regard to *Erysiphe graminis*.[35] This parasite grows upon grasses of the genus Bromus. He has proven that it contains many different strains that grow only on different species, each on its own species host. On six different species of Bromus, which for convenience we will designate as A, B, C, D, E, and F, he found six different strains of Erysiphe, which we will call *a, b, c, d, e,* and *f*. He found that *a* would grow on A and on F but on none of the rest. He found that *b* would grow on B and F but on no other of the lot. On continuing his experiments he discovered that *c, d,* and *e* behaved similarly to *a* and *b,* in that they would grow on their own hosts and on F but on none of the others. The "soil" of F was favorable to all, but the "soils" of A, B, C, D, and E were all antagonistic to each other's parasites. When, however, the parasite *a* was grown for several generations on F, Salmon found that it could then, with a little coaxing, be caused to grow upon B, C, D, and E. The same was later found to be equally true of *b, c, d,* and *e*. After growth on F they were cross-transferable to the other hosts. Because of this F came to be called a "bridging host." The host F was, evidently, intermediate in its posionousness to the parasites of the other hosts. These others varied away from F as five main branches of a tree would bend away from its central trunk. As all of the six species belong to the same genus (Bromus) they are, phylogenetically, branches of a common evolution trunk. This conceded and it is evident that parasites and hosts have varied *pari passu*. In obedience to the common rule the parasites varied least. With increase in the alien character of the grasses toward each other's parasites, they gradually must have ceased acting as cohosts until, finally, only F retained this power. The spores of the parasites being wind sown every one of these hosts stood a fair chance of serving as a cohost but refused to do so. Each parasite perished on all except its own host. When all of the six hosts began to deviate from each other their proteins had no destructive action on any of the six parasites. Then their tissue structure was chemotactic for the parasites. Naturally the parasites throve at the expense of the hosts and threatened their extermination. Each varied in its own way, but only those that varied in a manner destructive to enough of the parasites to save themselves from destruction were able to survive and perpetuate their kinds. Each host's type of poisonousness left unkilled such type of parasite as was best able to resist that form of poisonousness. As the change in each instance obeyed the law of chance each of the six hosts saved a different strain of parasite for itself. These settled down into a balanced neutrality that caused only chronic disease following weakness or injury. The proteins of the hosts ceased being immediately poisonous to their parasites because of this balance. The poisoning became anaphylactic, only killing when too rapidly digested and, therefore, too dangerous to the host. Here we see the probable genesis of anaphylaxis. In no instance does anaphylactic poisoning occur where there is not alien protein, and in no instance does it occur with alien protein until intercellular digestion is immediate and excessive. Every alien protein has arisen,

phylogenetically, from some nonalien common progenitor. Go back far enough and organisms that now produce proteins that are alien to each other produced proteins that were identical. The only persistent, causative agent known to us that could, by natural selection, produce anaphylaxis is parasitism. No other can be thought of that has selective value. In a former article in the MEDICAL RECORD the writer has shown that protozoan parasites have exactly the same kind of branching, paralleling the branchings of the higher animals, and extending from the lowest up to man,[36] as that seen in the relations of Erysiphe and Bromus. The parasites match every branch with a corresponding branch of their own, clearly indicating the probability of both having evolved together. Since anaphylaxis follows these very branchings it seems fair to infer that it has been caused by the selecting that followed the branchings. That selecting could only be due to parasites. Another phenomenon of parasitism that seems to confirm this view is that known to mycologists as heterœcism.

In the great Natural Order of Fungi, called the Uredineæ, over 2,000 species have been described and every individual of every one of these species is so absolutly dependent on parasitism as to perish in every place except on the few select hosts each parasite lives upon. The winds waft their countless millions of spores in every direction, but only those live that fall on their specific hosts. Among these species 150 have been found that live two quite unlike lives, each on a host of its own.[37] The two hosts belong to very unlike kinds of plants and they cannot be substituted for each other. The two forms of the same parasite require each its own specific host and cannot live if crossed upon its own hosts. So unlike are the two forms of the same parasite that mycologists long believed them to be entirely different kinds of plants. They develop alternately into each other from spores, much as if cabbage seed should grow into turnips and turnip seeds back into cabbages again, repeating the cycle indefinitely. For a plant to thus split its hereditary qualities into two or more parts constitutes heterœcism.[38] Massee thus describes the changes of *Puccinia graminis,* one of the fungi here referred to. "The aecidospores will not directly infect a barberry plant, but when placed on a leaf of a suitable grass infection takes place, and in due course pustules of uredospores appear on the surface of the grass leaf. Uredospores, on the other hand, will only infect grasses, and the production of uredospores and infection of new grasses continues throughout the summer. During the autumn, when the host plant is on the wane, the mycelium, that up to the present had been producing uredospores, now commences to produce teleutospores. * * *. The production of teleutospores completes the cycle of development of the fungus. The following spring the teleutospores germinate, infection of the barberry follows, and the cycle of development commences anew."[39] Let the reader remember that the proteins of barberry and grass are thoroughly alien toward each other if they obey the usual law. That they do obey this law is made probable in that the fungi that will grow on one cannot grow on the other. If the runners (stolons) of a strawberry plant acquired the habit of growing on a different kind of soil from that which would grow the seeds of the strawberry we would have a first step toward a condition akin to heterœcism. If the seeds from such stolons required the original soil on which to grow, a second step would be taken. By successive steps such as these we can imagine a possible origin of heterœcism. But it must begin on soil that is the same and that slowly changes in its poisonousness. No mutations jump into existence with such perfection in adaptations to totally unlike conditions. If at some time in the past barberry and the host grass on which a given species of *Puccinia* grows were evolved from plants of the same species, we can see a possible origin of this dual nature. But this means that heterœcism is as old as the barberry and grasses and that it evolved at the time they separated from each other.[40] Propinquity of barberry and grass might, as a doubtful possibility, under conditions of lowered vitality in the newest of the two hosts, favor parasitization, but for the production of heterœcism such an explanation seems wholly inadequate. For the production of such a phenomenon the most perfect adaptiveness of the parasite to both hosts appears to be a necessary prerequisite condition of its establishment. Unless the ability to cross from one host to the other was perfect from the beginning the conditions favorable for the transformation of the parasite into its two forms would be absent. Another and apparently much more ancient illustration of heterœcism is seen in various species of the genus *Gymnosporangium* that have as hosts different species of the rose family on one side and of junipers on the other.[41] In both *Puccini* and these the alternation of generation resembles in several respects the case of *Plasmodium malariæ* and its two hosts, man and mosquito. All of them involve the problems of genesis and antiquity. In the *Plasmodium* we can trace the successive steps of the modifications of its sporozoan kindred, by which it evolved from a parasite of intestinal epithelial cells to a parasite of red blood cells, and from a parasite of wholly cold-blooded animals to one of alternation between cold and warm-blooded animals. In the mosquito it is still an epithelial parasite as well as a cold-blooded one.[42] The transition picture is quite like that of plant heterœcism. In both one of the hosts is very much higher in the scale of evolution than the other. No hypothesis can cover the facts that excludes great antiquity or divergence in evolution of the two hosts. Evolutionists must concede divergence in descent or stultify themselves, and paleontology fully confirms the claim of parasitic antiquity. Many fossil plants of a far greater antiquity have been found in which fungi can be seen as parasites piercing the tissues of their fossil hosts. Meschnikelli has drawn and described over 400 species of very ancient fossil fungi. Massee tells us that "numerous Ascomycetes, Pyrenomycetes, and Dyscomycetes occur on (fossil) leaves, and in the tissues and stems of many different (fossil) plants, in some instances so well preserved that the structure of the perithecia with their conidia or spores can be studied."[43] Evidence of this convincing character can hardly be seriously questioned. Parasitism, then, is older than our modern dominant flora and older than the higher vertebrates. How much older we can only conjecture.

On the assumption of the ubiquitousness of parasitism and its indefinitely great antiquity let the reader endeavor to picture to himself a few of the important implications which this implies. To perceive that a continuous menace of disease and death, due to disturbances of the universal balanced, armed neutrality of chronic parasites, has,

probably, for many millions of years, hung over all organisms, is to get a new illumination regarding the mechanism of natural selection. No other known agent could possibly have been in action so long. No other has stuck so persistently to the task of selecting for destruction unfit germ plasm. No other has become adjusted to this task with any approach to the delicacy with which this selecting agent can work. Parasitism acts directly upon the *molecular structure* of every cell. Parasites feed upon cell molecules so that the survival of cell molecules is the one all-important event in the life of every creature. It is for these that the hungry parasites fight with the cells. It is to these that both parasite and host are indebted for their existence. These facts constitute our evidence that the cell molecule holds the chief and all-important place in natural selection. The over-destruction of these molecules always means the extinction of the race of cells or organisms that possess them. Let the molecules change in ways that will increase their attractiveness for microbes and it needs no prophet to foresee the dire consequences that must follow. Let them lose their power of repulsion, and thus convert them into favoring food for parasitic multiplication and the organism that produces them is foredoomed. Let them become more repulsive or more poisonous and the chances of a destructive invasion of their parasites is instantly lessened. Molecules that have varied in this way are a shield of defense for their producers. Who can doubt that an organism which varied in a way to increase its attractive molecules would soon be swept from the earth? Who, conversely, can doubt that an organism that varied in a way to increase its parasite repulsing and parasite poisoning molecules would be the better able to survive invasion? Not to be thus fit spells speedy extinction. Every cell in every organism—germ cells not excepted—and every minute organ of every cell is built of molecules that are potential food supplies for microbes. The only evident reason why all cells in every one of the higher organisms are not swept out of existence is because their molecules (*a*) have varied in ways that poisoned parasites, (*b*) have become repellent to the parasites, (*c*) have produced antienzymes to arrest the digestive powers of the parasites, or (*d*) have taken refuge behind molecules possessing one or other of these qualities. The only evident reason why parasites have not been exterminated by the cells is because they have become adapted, one by one, to every, to them, injurious variation in their hosts and checkmated the hosts by similar variations of their own. As Massee says, "It is always well to remember that however much the host plant may succeed, aided or unaided, in guarding itself against its foe, fungi, on the other hand, have proved themselves equally capable of adaptation to existing circumstances."[44] During millions of years this shifting of fitness, first to one side and then to the other, has kept up one incessant round of changes in the molecules of both host and parasite, which selection has preserved. Every germ cell that failed to change its molecular panoply so as to hold back the destructive influences of invading parasites has perished, unrepresented. While most of the damage and destruction of germ cells seems, at present, to be accomplished by the cytotoxins acting through the general circulation, we have evidence, particularly among the lower vertebrates, of these cells being subject to direct attack. There are species of Coccidium that make their homes in testes, others in ovaries, and still others in the vas deferens. There are species of Glugea that select the gonads, while others limit themselves to the ova, and still others to the sperm cells. There are species of Zygocystis, of Monocystis, of Spermatophagus, and of Uraspora that confine themselves to the vesiculæ seminales. There are Legerella that prefer the testes, Rhabdospora and Pleistophora that choose the ovaries, and Myxosporidia that limit themselves to the ova.[45] These bring us down to the bed rock of the mechanism of natural selection. When a whole individual is selected because of his fitness we can gain no conception of how the fitness arose. Within a human being that is about to be selected under some new condition of his environment any new fitness that may arise must be fitly correlated with countless millions of prior fitnesses. If these correlations could arise through chance variations, why may we not ascribe wholly to chance, and independent of natural selection, the entire process? If the changes came as slowly gained molecular adjustments, through the selective action of parasites, the thing is understandable. Unless molecules are subject to natural selection cell organs and cells are produced wholly fortuitously. Unless molecules, then cell organs, then cells, then tissues, then organs, and finally organisms are each, by successive molecular selections adjusted to each other then every organism must be a product of pure fortuitousness. But, if any or all of these steps are wholly fortuitous then miracle rules, miracle produced mutants are a certainty, and natural selection a chimera. But, as even mutationists concede that natural selection controls the final destinies of their mutants, why deem mutation a miracle? In landslides, where water slowly undermines the supports of the land, we do not invoke miracle as an explanation. We look to gravity and the undermining water. Why, then, refuse to see the gradual undermining work of parasites among the organic molecules that has been going on for time so long as to baffle imagination. Mutants are exactly such phenomena as we might expect among gradually changing protein molecules, subject to the law of mass action. Out of molecules the whole body is built. By altering molecules any conceivable change may be produced. Mutations can only be due to variations among the molecules. That the molecules are, and ever have been, subject to selection, we have no reason for doubting. Parasites have never ceased their work of selecting them since competitive life first appeared upon our planet. Every selection made has been for cause. No molecule has been selected for extinction until it and its kind have jeopardized the existence of the organism. Every selected fit variation has been of molecules that have strengthened constitutional resistance to adverse climatic conditons, to fatigue, to excessive strain in the search of food or the subduing of foes, to hunger, to wounds and bruises, in fact to everything that established unfitness. Each of these favored the breaking of the armed neutrality of the parasites and caused attack. Whenever soma cells gave way before these parasites the germ proteins and carbohydrates of like kind had to give way and change or die. As soma cells always give way to every condition of change which demands readaptation germ protein and germ carbohydrate

had to give way at the same time. Thus it happens that during the phylogeny of every organism the very changes occur that are required to occur to produce new and adapted forms. The body responds by disease to unfavorable conditions and the parasites rid the germ cells of the unadapted molecules that made such disease possible. This incessant parasitic attack of the organism along the lines of its least resistance, and always where excessive strain appears, is, the writer believes, the unknown element in natural selection which Osborn and other evolutionists have insisted upon the existence of for so long. Professor Osborn says: "I came to the conclusion in 1895 that we must appeal to the existence of some unknown factor or factors of evolution. Subsequent research has convinced me that in these phenomena of the internal origin first of certain determinate characters, we are dealing with the unknown if not the unknowable, although the latter despairing attitude should not be hastily adopted."[46] The selection by microparasites is the only selection that is known to select, step by step, every part of every organism with incessant fidelity through countless generations. By selecting molecules they select cell organs, cells, tissues, organism organs, and the entire organism whether plant or animal. The selecting has been done bit by bit and so presents to the mind the problem of natural selection free from the terrible ambiguity attached to the same problem where whole organisms only are considered. It provides for perfect correlation of all the parts from the inconceivably minute molecules upward. Such selection most probably began at the very birth of living matter and has never ceased its operations from that day to this. Any part of any organism, great or small, that showed a weakness under any new condition of its environment, became the immediate point of attack by disease, and had either to vary in conformity with the new demand of that environment or the organism had to submit to extinction. Under great stress the selection was of individuals. Under less severe stress the attacked organism did not have to die to bring favorable selection, as such conditions kill and maim germ cells, thus making the selection through them. Germ cells, in common with soma cells, are built of hydrolysable molecules. There is absolutely no difference in the chemical principle involved in their dissolution and in the dissolution of the soma cells. The reversibility of enzyme action indicates that any organism that can construct germ plasm ought to be able to destory it by reverse action. Differences in molecules are due to differences in detail, but in all the molecules of living matter the hydroxyl and hydrogen ions of water cement them together out of varying numbers of the same kinds of amino acids. Germ cells are destroyed under infection. They are also injured under it. Why should there not be degrees of such injury and degrees of fitness in resisting the poisoning and digesting powers of parasites? The germ cells contain proteins, fats, and carbohydrates that the parasites digest and use as food. It is these they are after, and it is a question whether or not they have any great choice as to where they can get them. Those molecules that, to a given parasite, are most easily digested will be the first to suffer and all cells of the body in varying degree. To the various species of Spermatophagus the spermatozoa of their hosts is the most desirable morsel, because it is the part to which their digestive enzymes have become adjusted. Whether the struggle between the parasites and the germ cells is direct or indirect the selection occurs in response to lack of resistance in that germ cell which is damaged. Its lack of resistance is toward the enzymes and toxins that are being used by the parasite against soma cells having the same weakness. The surviving germ cells are those with the minimum number of molecules hydrolysable in the way that the diseased part of the body is being hydrolysed or injured by the toxins that injure the soma cells. That the morphological changes have comported with the chemical changes in the surviving molecules is a reasonable inference from what we know of the relations of crystalline forms and other qualities to chemical structure.

## ULCEROMEMBRANOUS ANGINA (VINCENT'S) AND ITS TREATMENT; WITH REPORT OF CASES.*

By CHARLES CLYDE SUTTER, M.D.,

ROCHESTER, N. Y.

No disorder is more readily demonstrated, more frequently overlooked, or if noticed, oftener neglected in the scheme of therapeutics than mouth infections. No practical physician can deny the influence of this condition in the production of forms of arthritis, in endocarditis, in inflammation of the pharynx, in chronic excessive intestinal putrefaction, in toxic anemias, in some obscure, mild, long-continued fevers, in toxic nerve disorders, as neuritis, and in many functional disorders of the nervous system, which are toxic in origin. Its influence on the prognosis of pneumonia, typhoid fever, and other infectious diseases is not questioned, yet the therapeutics of buccal disease is in a comparatively unsatisfactory state, notwithstanding the ease with which the mouth can be inspected, its secretions tested and remedies applied. The process may be local or general. It may be limited to the vicinity of one tooth or extend throughout the mouth. If present, it may be indicated by a carious tooth, by an abscess, or by an inflammation at the root of the tooth. More evident processes are seen in gingivitis, in stomatitis (catarrhal suppurative, ulcerative and ulceromembranous), in pyrrhea alveolaris, in tonsillitis, and in ulceromembranous angina.

My interest in mouth infections was stimulated during my service as physician to the Philadelphia Hospital for Contagious Diseases in 1910 where I had the opportunity of studying the throats of from 50 to 200 patients daily. My first cases of Vincent's infection were seen at this time; the others were seen among the servants of the Glen Springs Sanitarium and in my private practice.

In this paper I wish to record my experience in fifty distinct cases of ulceromembranous, or Vincent's angina and supplement with a review of the literature.

I have examined the latest textbooks of medicine for a description of this infection. The majority of the authors either fail to mention this infection, or else confine their discussion to but a few lines. Most of the articles on this subject in the medical journals contain reports of the unusual cases rather than the ordinary ones.

Without a doubt this tonsillar and pharyngeal affection is treated more frequently than any other mouth infection, without a correct diagnosis having been made. Many times a positive diagnosis would be made if, in addition to cultures, smears were made from the ulceration. Some cases have even received salvarsan before smears were made, showing the fusiform bacilli and spirilla of Vincent. The failure of many laryngologists and pediatrists to recognize this infection is due to their attention not being especially called to its clinical features and because of the mildness of symptoms in many cases.

Blühdorn[1] has examined the throats of 222 patients for fusiform bacilli and spirilla and found one or the other or both in all but 27 of 76 patients with diphtheria; in all but 31 of 42 cases with scarlet fever; in all but 13 of 26 cases of streptococcus or staphylococcus sorethroats; in 2 of 4 cases of ulcerative stomatitis; in all but 10 of 31 cases of syphilitic mouth or throat lesions; and in all but 18 healthy persons.

The cases reported by Holm[2] were gathered during 1908 and occurred among 265 cases of suspected diphtheria examined at the Laboratory of the Michigan State Board of Health. *Bacillus diphtheriæ* was recorded whenever present, regardless of the relative number. *Bacillus fusiformis* was recorded only when found by direct smear from the swab to be more numerous than any other. The total number of cases examined for diagnosis was 265, showing *Bacillus diphtheriæ*, 118; *Bacillus fusiformis*, 73; a membrane was described in all but 4 cases; involving both tonsils, 38; one tonsil, 31; extending to adjacent structures, 15. The color of the membrane was given as gray, or grayish, 41; yellow, 9; white, 8; grayish yellow, 1, and creamy, 2. The highest temperature given was 103.6° F., the lowest 98.5° F., the average being about 100.5° F. The clinical diagnosis was given as diphtheria, 28; suspicious or questionable, 20; tonsillitis, 17; Vincent's angina, 5, and scarlet fever, 1. The cultural results showed streptococci, 29; staphylococci, 20; *Bacillus diphtheriæ*, 14; *Micrococcus catarrhalis*, 8; pneumococci, 1; Hoffmann's bacilli, 1. In the entire series of 265 cases diphtheria was diagnosed on clinical grounds in 99. The bacteriological examinations of these 99 cases showed *Bacillus diphtheriæ* present in 64 cases, absent in 35 cases. Among the 73 cases showing *Bacillus fusiformis*, diphtheria was diagnosed clinically 28 times. The bacteriological examination of these 28 cases showed *Bacillus diphtheriæ* present in 1, absent in 27. This gives a percentage in the clinical diagnosis of diphtheria in the presence of *Bacillus fusiformis* of 96.4. The cultural results in this series of cases indicate that streptococci and staphylococci are the most usual in the cases of Vincent's angina. It should be further noted that, in over three-fourths of the cases of pseudodiphtheria, the direct smears from the membrane showed a predominance of *Bacillus fusiformis*.

Vincent's angina usually occurs between the ages of 2 and 25 years. It is more frequently seen in damp weather, especially during the spring and autumn. Such conditions as oral uncleanliness, local irritative lesions in the mouth, dental caries, inflamed gums, alveolar abscess, syphilis and mercurial stomatitis, acute infectious and contagious diseases, enlarged and necrotic tonsils, trauma after tonsillectomy, etc., favor the development of the disease. Contagion has been observed, but close contact is apparently required as by means of pipes, pencils, drinking and eating utensils.

Vincent's angina consists of an inflammatory lesion in the mouth, pharynx, or throat, situated most frequently upon the tonsils. It usually begins as an acute stomatitis, pharyngitis, or tonsillitis. This soon leads to the formation of a granular or cheesy pseudomembrane, which, at this stage, has a great deal of resemblance to that caused by the diphtheria bacillus. This false membrane may be removed by scraping, leaving bare a reddish and bleeding surface. At later stages of the disease there may be distinct ulcerations. The shedding of this pseudo-

*Read before the Pathological Society, Rochester, N. Y., November 14, 1912.

membrane leaves a deep anfractuous ulcer with prominent edges, which, clinically, has often been erroneously diagnosed as syphilis. The lesion commonly involves one tonsil and may spread to the soft palate, the other tonsil, the pharynx, or the gums. It may even spread to the larynx or trachea in children. In scarlet fever patients I have seen it involve both pillars of the fauces, the tonsil, and the lateral wall of the pharynx, extending for a short distance into the nasopharynx. The ulcers do not, in themselves, comprise the entire lesion. Softening and swelling of the mucous membrane of the gums, which become grayish and bleeding, has also been observed. Some authors have confounded this form of stomatitis with scurvy. It is evident that the disease is not simply a stomatitis, it is an ulcerogangrenous inflammation of the whole buccopharyngeal cavity. The ulceration at times is very destructive, destroying the whole or a portion of the tonsil, and invading healthy tissue. The tendency is to extend laterally instead of deeper. A curious fact is the rapid recurrence that takes place when the membrane is removed, so similar to the membrane of diphtheria. In a number of cases reported the tonsils have been amputated but, in each case, the wound became infected with the same organisms. The submaxillary, retromaxillary, and cervical lymphnodes are often markedly swollen and tender, but rarely suppurate. In scrofulous subjects they may persist indefinitely. The disease is acute or subacute and often becomes chronic, the ulcers persisting for weeks or months. One attack is likely to be followed months or even a few years later by a recurrence. Infection takes place only when the mucous membrane is abraded and it often becomes engrafted upon a preceding attack of amygdalitis. There may be no constitutional disturbances, the patient complaining only of more or less pain in swallowing, or he may have discovered the yellowish patch on examining his throat with a mirror, because of a slight feeling of discomfort. Again the symptoms are most violent—great pain in mastication and deglutition, breath fetid, saliva profuse, more or less gastrointestinal disturbances, submaxillary and cervical lymphnodes enlarged and tender, and neuralgic pains in the side of the face and neck, sometimes even extending to the chest. The temperature varies from normal to 102 deg. While resembling tonsillitis, the following points of difference are noted: The absence of rise of temperature, the constitutional symptoms are at variance with the amount of lesion seen, and the pain is more localized on the affected side, being quite severe and lancinating.

The depression of the patients in some cases is very marked, so much so that the patients are completely prostrated, out of proportion to the clinical manifestations of the throat lesions. The depression is not present in a marked degree except in cases where the membrane covers a large area of the tonsil or pharynx and is of the heavier type. The cause of such prostration has not so far been ascertained.

The most peculiar characteristic is the absence of rise in temperature, for all other tonsillar invasions, even those of less area involved and apparently of less virulence, are associated with rapid rise in temperature. The absence of this symptom is one of the most constant signs, and is especially difficult to explain in the face of the great malaise and exhaustion which are usually of toxic origin. The localized pain simulates very much that of quinsy; in fact, oftentimes, from the patient's appearance, we have made a tentative diagnosis of peritonsillar phlegmon, this being dispelled on examination.

Case I.—An example of this type is seen in the case of a girl, aged sixteen years, who gives a history of having had, during the past three or four years, about ten to twelve attacks of quinsy. I was consulted April 18, 1912, for a recurrent attack. Upon examination I found the neck swollen and tender on the left side, the left tonsil and pillars of the fauces swollen, and an ulceration covering the lower half of the tonsil. This ulceration was filled with a grayish, cheesy pseudomembrane. There was considerable pain in deglutition, neuralgic pains in the face and neck, headache, chilly sensations, and marked general depression. The temperature varied from normal to 99 deg. F. The pulse was not accelerated. Microscopically, by means of smears, fusiform bacilli and spirilla (Vincent) were found in large numbers. Treatment was instigated and the patient improved rapidly. At the end of the first week the patient refused treatment, thinking it was only the "ordinary sore throat" and would get well without further treatment.

Three weeks later I was again summoned. This time both sides of the neck were quite swollen and tender, the tonsils enlarged until they almost met in the midline, and the ulceration was now located on the lateral walls of the pharynx. There were severe lancinating pains in the face and neck extending to the chest, difficult mastication, deglutition almost impossible, inability to sleep because of difficulty in breathing, and depression so marked that the patient was confined to bed for several days. The temperature and the pulse were again normal. Smears made from the ulceration showed almost a pure culture of fusiform bacilli and spirilla. Treatment was again instigated and the patient improved rapidly. The diagnosis of ulceromembranous tonsillitis and pharyngitis was made in this case because of the "punched out" appearance of the ulcer, the absence of rise in temperature and accelerated pulse, the presence of almost a pure culture of fusiform bacilli and spirilla, the disappearance of these microorganisms with the symptoms and their return with the return of symptoms.

Case II.—This patient was a man, aged twenty years, who complained of toothache. This gradually became so severe and the depression became so marked that the patient had to quit work, and consulted me for relief of symptoms until he could go to a dentist. Examination of the mouth revealed an ulceration of the mucous membrane on a level with the last molar teeth. The ulcer was filled with necrotic material which was slightly adherent. The temperature was normal and the symptoms were out of proportion to the amount of lesion. Fusiform bacilli and spirilla (Vincent) were found in large numbers. Under treatment the symptoms disappeared in a few days. Diagnosis—Ulceromembranous stomatitis.

Case III.—Man, aged twenty-seven years. History of sore throat, painful deglutition, and malaise for two or three days. Examination of the throat showed the left tonsil to be swollen and partially covered by a grayish membrane. The temperature and pulse were normal. Cultures were reported negative for Klebs-Löffler bacilli. Smears showed almost a pure culture of Vincent's spirilla

and fusiform bacilli. Under treatment the ulceration was healed in ten days. Diagnosis—Ulceromembranous tonsillitis.

Case IV.—Child, aged two years, admitted to Ward B of the Scarlet Fever Department of the Philadelphia Hospital for Contagious Diseases on the second day of the disease. At that institution routine examinations are made of the throat of all patients daily. In this case examination revealed an extensive ulceration involving almost the entire right tonsil, both pillars of the fauces, the right lateral wall of the pharynx, and extending for a short distance into the nasopharynx. The right submaxillary and retromaxillary glands were enlarged and tender. Temperature 102 deg. Cultures were negative. Smears contained Vincent's microorganisms in almost pure culture. Swabbing of the ulceration was done with cotton saturated with hydrogen peroxide and wrapped around the index finger. After all the necrotic material was removed, a 10 per cent. solution of copper sulphate was applied directly to the ulcer. Following this a saturated solution of potassium chlorate was used. No fusiform bacilli or spirilla were found after the seventh day of treatment. The ulceration was completely healed in about three weeks, leaving practically no scar tissue. Diagnosis—Scarlet fever and ulceromembranous pharyngitis.

These cases were selected as representing the different ways in which Vincent's angina is manifested.

For a long time this infection has been confounded with other infections of the mouth under the misleading names of stomacace, chancre, scurvy, membranous stomatitis, etc. The nature of the lesions of this peculiar kind was not clear until Plaut,[3] Vincent,[4] and others reported uniform bacteriological findings in cases of this description. These observers demonstrated in smears from the lesions a spindle-shaped or fusiform bacillus, and a spirillum not unlike the spirillum of relapsing fever. The two microorganisms are always found together in this form of disease and were regarded by the first observers as representing two distinct forms dwelling in symbiosis. More recently Tunnicliff,[5] on the basis of experimental work, has claimed identity for the two forms, believing that they represent different developmental stages of the same organism.

The fusiform bacilli are from 3 to 10 micra in length and have a thickness at the center varying from 0.5 to 0.8 micron. From the center they taper gradually toward the ends, ending in points. The lengths of these bacilli may differ greatly within one and the same smear preparation. They are usually straight, sometimes slightly curved. MacWhinnie[6] describes them as resembling canoes with often transverse markings that somewhat resemble the seats of the canoe. Stained preparations show a characteristic inequality in the intensity of the stain, the bacilli being more deeply stained near the end, and showing a banded or striped alternation of stained and unstained areas in the central body. Their staining qualities in this respect are not unlike those of the diphtheria bacilli. The bacilli are nonmotile. They have not yet been isolated in pure culture, although Vincent was able to make them grow in bouillon with other organisms from the mouth. It is a saprophyte of the buccal cavity, but becomes pathogenic in the presence of other organisms. Fusiform bacilli morphologically similar to those found in the angina of Vincent have frequently been found in smears taken from the gums, from carious teeth, scurvy, and noma.

The spirochetæ, or spirilla, are usually somewhat longer than the fusiform bacilli, and are made up of a variable number of undulations. They are shallow and irregular in their curvatures, unlike the more regularly steep waves of the *Spirochæta pallida*. By the earlier observers, cultivation of these microorganisms was attempted without success. Recently, however, it has been shown that cultivation could be carried out under anerobic conditions. Tunnicliff[5] has cultivated them anerobically upon slants of ascitic agar at 37.5 deg. C. This observer found that in such cultures, before the fifth day, bacilli only could be found, that after this time, however, spirilla gradually appeared and finally constituted the majority of the organisms in the culture. It appeared to Tunnicliff from this study that the spirilla might be developed out of the fusiform microorganisms representing the adult form.

The spirochetes that may lead to confusion with the spirillum of Vincent are the *Treponema pallidum*, the *Spirochæta refringens*, and the *Spirochæta dentium*.

*Treponema pallidum* is an extremely delicate undulating filament from 6 to 14 micra in length by 0.25 micron in breadth. Its convolutions vary from 6 to 26 extremely close and fine turns; the ends are pointed and a flagellum has been described at each extremity.

*Spirochæta refringens* is not found regularly and is not pathogenic. It is strongly refracting and its color with Giemsa's stain is blue, and not pale rose. It is easily distinguished by its coarser contour, its greater thickness, its less numerous undulations and by its ends being more blunt.

*Spirochæta dentium* is also shorter and thicker than *Treponema pallidum;* the ends are more blunt; flagella-like ends are less common; the spirals are flatter, less regular, and narrower. To many observers these points of difference are so fine that many times it is almost impossible to differentiate them. *Spirochæta dentium* is found only on the surface, so it is quite important to remove the surface layer of a lesion and examine the serum from the deeper parts, being careful to prevent surface contamination. This practically eliminates *Spirochæta dentium*. If a spirocheta is demonstrated that is over 10 micra in length we may be reasonably certain that we are dealing with the organism of syphilis. If both a fusiform bacillus and a spirillum are found in almost pure culture we can make the diagnosis of Vincent's infection.

The microorganisms of Vincent's angina, when occurring in the throat, are rarely present alone but are usually accompanied by other microorganisms, such as staphylococci, streptococci, and not infrequently diphtheria bacilli. If pseudodiphtheria organisms are present, we have them showing a gram positive reaction. It is not yet determined whether the disease is due to the fusiform bacillus alone, or whether the spirillum plays any part; the spirillum may possibly be merely a morphological variation of the bacillus. The fusiform bacillus is occasionally found alone, but the spirillum never.

The large number of fusiform bacilli and spirilli in the false membrane, the reproduction of the membrane as long as these microorganisms are present, and the clearing up of the mucous membrane as soon as they commence to decrease, are sound arguments for admitting their action in the genesis of this disease.

The diagnosis in all cases should be made with microscopic slides, consisting of smears from the membranes, which require but a few minutes. The superficial, necrotic pseudomembrane should be removed gently and a smear made from the underlying fluid. This should be fixed and stained in the ordinary way. Any of the aniline dyes may be used, but they are more readily stained by Löffler's methylene-blue, saturated aqueous solution of gentian violet, Giemsa's stain, or India ink. They are usually decolorized by Gram's method. Stained preparations show a characteristic inequality in the intensity of the stain, the bacilli being more deeply stained near the end, and showing a banded or striped appearance. The occurrence of the bacilli may be irregular, often occurring as tetrads, presenting vacuoles and other degenerate forms. The spirilla are stained with more difficulty than are the bacilli and usually appear less distinct in the preparations. The stain, however, is taken without irregularity, showing none of the apparent metachromatism observed in the bacilli. The fact that so many cases of ulceromembranous tonsillitis are not recognized is due to the fact that immediately the membrane becomes evident a culture tube is brought into service and the case is subjected to the routine of a diphtheria case. These microorganisms will not grow on the ordinary culture media; so many times the report comes back negative when the case is really one of ulceromembranous angina. Other cases are overlooked because the symptoms usually complained of are not always present and because there is usually no rise in temperature. Smears should always be made in every case of suspected diphtheria. In suspected syphilis, in both the secondary and tertiary stages, an examination of a smear would clear up the diagnosis. Here we must be very conservative in reporting such an organism because of the similarity of the morphology of the *Treponema pallidum*.

The prognosis is usually good. The rapidity with which healing of the ulceration takes place following the disappearance of the membrane is striking, as a rule, leaving no manifestation of the previous condition. This applies to the superficial as well as to the deeper ulcerations. Sometimes the disease tends to persist for several weeks, and may recur at any time. Complications are seldom troublesome, and a fatal issue is not to be expected unless the larynx or trachea becomes invaded in a child. The adenitis which often accompanies this process disappears readily, usually in six to ten days after healing has taken place.

The treatment of this disease is very simple but must be thorough to be effective. The necrotic material or pseudomembrane should first be removed by swabbing the ulceration with hydrogen peroxide, full strength, or diluted half, until the ulcer is clean. Then either a 10 per cent. solution of copper sulphate followed by a saturated solution of potassium chlorate, or tincture of iodine should be applied directly to the ulcer. Iodine is probably the best local agent for destroying the bacteria and at the same time promoting healing of the ulceration. The drugs recorded as used by different authors are: Silver nitrate, subacetate of copper, chromic acid, carbolic acid, argyrol, iron and glycerine, methylene-blue, zinc sulphocarbolate, and local application of salvarsan. The galvano cautery and chemical cauterizing agents have been used without much success. An astringent cleansing mouth wash is indicated. Potassium chlorate should be used either locally or internally. Most relief from the pain in swallowing will be obtained from the use of orthoform in powder or tablet form. General tonic treatment is indicated only in multiple stomatitis and in the recurrent forms. To prevent infecting others, drinking and eating utensils should be sterilized and kept separate. Sputum and mouth discharges should be burned. Following the attack, local disease of the mouth, teeth, and tonsils should be attended to, but operative work had best be postponed until making sure, by the microscope, of the absence of the specific bacteria. Removal of the tartar from the teeth and oral hygiene are important as preventives.

*Relation of Mouth-Disease to Disturbance of Metabolism and Systemic Disease.*—The physician, whenever he is consulted by any patient, should examine the mouth carefully, and give advice for daily continued cleanliness; the character of the solutions he deems advisable to order depending on the condition in which he finds the mouth. The frequency of the agency of the mouth in the production of diseases is almost altogether overlooked. Its importance in diagnosis is only beginning to be recognized. How often do we find pathological conditions in which the most minute examinations of the blood and urine are made, the temperature, the pulse, the respiration, and other conditions carefully noted, while the diseased mouth, reeking with dangerous microorganisms, is overlooked as having no bearing on the case. Treatment of septic disorders is greatly retarded and, in certain cases, rendered altogether impossible by the neglected condition of the mouth. The mouth seems to be splendidly arranged for the propagation and even the protection of bacteria. There are cavities, caverns, and crypts, not easily cleansed, which are moist and warm, and more or less food is deposited near or in these spaces, which forms suitable pabulum for the growth of bacteria. Accumulation of infectious matter in the mouth may easily become the origin of disturbances of varied degrees of intensity in the most vital portions of the alimentary tract. It has been shown that some of these pathogenic bacteria may cause not only intestinal indigestion and putrefaction, but may even be a source of pernicious anemia. A normal gastric juice kills most of these germs which are swallowed, but anything which alters the secretions will allow these germs to be carried into the intestines unharmed, where they can continue to grow. Mouth infection influences the prognosis of pneumonia, typhoid fever, and other infections. It adds immensely to the gravity of the case, not only because of the existing local disorders, but because of its past effect on the organism. The resistance and the nutrition are influenced. There is always the danger of reinfection because the organisms may be harbored in the tooth cavities and crypts. In anemia, chronic toxemia, arthritis, chronic gastrointestinal conditions, etc., the course is in accordance with the degree of success attained in the treatment of the primary mouth disorder. Oral antisepsis is a field of preventive medicine which must be worked out by the combined efforts of the physician, the dentist, and the patient.

## GONORRHEAL OPHTHALMIA TREATED WITH GONOCOCCUS VACCINES.

By W. K. MITTENDORF, M.D.,
NEW YORK.

A study of the character of the discharge in gonorrheal ophthalmia with the microscope, noting the morphology of the bacteria and their location, led to the attempt to treat these conditions with the vaccines. Seeing that these bacteria were present in the cells of the conjunctiva and the cornea in small colonies, few of them being free and so few being actually found in the many pus cells in each field examined, the natural inference was that could there be an immunity established for the actual corneal and conjunctival cells below the outer layer, the disease should run a mild course without any serious complications and would yield more readily to the usual external treatment. The fact that these bacteria grow best or at all satisfactorily on blood serum cultures also was in favor of the treatment by rendering the serum of the patient a poor culture medium for their growth. The first nine cases so treated showed very marked results and the clinical history of these cases is here given for consideration. In all the cases treated there was a very rapid termination of the swelling of the lids and a decided lessening of the discharge, and in only one case were the bacteria found after the second week. Usually one felt that after the first couple of days all danger to the eyes was passed and that in a week or ten days the patient was as good as cured. Of these cases eight were treated in the Platt Pavilion of the New York Eye and Ear Infirmary from the clinics of Drs. W. E. Lambert, R. G. Reese, and L. W. Callan; one was treated at home in the country by the parents with equally satisfactory results.

Case I.—Max N., age 24. Lids and ocular conjunctiva red and swollen and much pus. Had gonorrhea and rheumatism of the knee and pains in hip. Smears were negative from each eye, but cultures made grew gonococci; after three days the smears from the eyes were positive and there was a beginning involvement of the right cornea with some haziness. This case was undoubtedly a metastatic condition. Put in hospital and gonococcus vaccine injected by hypodermic syringe with argyrol, 25 per cent., and boric acid irrigation locally. Previous to admission he had had this treatment but steadily grew worse. The vaccine injections were given every third day—first 50 million gonococcus and 200 million staphylococcus albus, the other doses double this amount. In forty-eight hours the swelling was gone in the lids and the eyeballs were almost white. The case steadily improved and the smears were negative in two weeks. The patient was held a week and discharged in three weeks with eyes well. The rheumatism had also disappeared. Two weeks later he reported he was again working as a butcher carrying heavy meats and on his feet all day with perfect comfort.

Case II.—Baby F., age 3 days; premature baby, 7 months. Both eyes were badly swollen and red, discharging much pus; had been using argyrol, 20 per cent., but eyes got much worse. Smears showed numerous gonococci. Baby small and weak and would take no nourishment. It was in the country and could not go to hospital so I decided to use vaccine of gonococci 50 million, pseudo Klebs-Loeffler 50 million, staphylococcus albus 100 million, streptococcus 50 million, colon bacillus 50 million. The first dose was one-third of this amount and the subsequent doses (at two-day intervals) one-half. After the second day the swelling in the left eye had disappeared and the baby was feeling better and took some nourishment. After the fourth day both eyes had lost all swelling and there was very little discharge. The next three days baby had almost no local treatment as the mother developed pleurisy and could not attend to it, but it lost no ground and opened both eyes nicely. In two weeks the eyes were cured and the vaccine was discontinued with only occasional local treatment. This baby was nourished hardly at all and was very weak during the whole course of treatment, but was not affected in any way by the vaccine injections and lived for seven weeks before it died of malnutrition on the approach of cold weather. The physician attending the family had not expected the child to live a week when it was born.

Case III.—Baby Wm. D., age 15 months. Had sore eyes about a week when taken to hospital. Both eyes were swollen and outside of lids very red and closed tight. Treated three days in hospital; no improvement. Same vaccine used as in preceding case in same dosage. On the second day after injection the baby opened both eyes, the swelling was almost gone, and the discharge was very limited. Vaccine was used at three-day intervals during the second week. Both eyes were closed again for one day and a small ulcer was discovered on the left cornea, but this was yellowish and raised, with no haziness of the cornea except in the limited area of the ulcer. Atropine ordered t.i.d. Two days later the ulcer appeared the same, but smears from both eyes were negative. As ulcer appeared phlyctenular I applied yellow oxide of mercury, gr. i, in lanolina 5iss, morning and night. The ulcer began to improve immediately and in forty-eight hours was healed. After six injections the patient was discharged cured.

Case IV.—John H., age 20 years. Old extensive macula in the right cornea from traumatism. He had posterior urethritis and rheumatism of knee, finger, and elbow. Both eyes were red and lids somewhat swollen with much discharge. Argyrol and boric acid irrigation was ordered, and a vaccine of 100 million gonococcus and 80 million staphylococcus albus were injected every three days. There was immediate improvement in both eyes. On the sixth day he had pain in the right eye and some redness—probably iritic irritation—as there was no ulcer on the cornea; this disappeared the next day. After six injections the patient was discharged, both eyes showing negative smears. After eighteen days treatment the rheumatism was almost all gone. After the patient had gone home his physician gave him a very large dose of vaccine, estimated at 250 million, but probably more. In forty-eight hours both eyes were red, all the joints were inflamed, and small ring of ulcers appeared on the left cornea. Smears were negative in both eyes. He was sent to the ward, atropine

was used, and a vaccine of 100 million gonococci was given. In three days the eyes and joints were better, and two days later the patient was discharged and walked out of hospital without a cane. Ten days later he reported all well in both eyes. He had danced all the preceding evening without any inconvenience at all.

Case V.—Max B., age 24. Right eye affected, very red, and swollen. He was five days in the ward getting worse under treatment with argyrol and boric acid, small ulcers appeared on the cornea, and there was a copious creamy discharge. Gonococcus phylacogen was injected on the fifth day, 5 c.c. subcutaneously. There was a marked reaction, the temperature going to 104°, but the eye improved, and after the second injection he could open the eye himself. Five daily injections of 10 c.c. were given, when the eye appeared almost normal, and the patient was sent home. He reports no relapse. After each injection the systemic reaction was less and of shorter duration.

Case VI.—John S., 4 weeks old. Treated three weeks at home. Perforating ulcer of the right eye. The left eye has been discharging four days now. Lids very swollen and copious thick creamy discharge. Smears from both eyes positive. Vaccine (100 million gonococci) used every three days, atropine to right eye, and argyrol and boric acid irrigation to both. Two days after admission the baby opened left eye; there was protusion of iris in the right with still some swelling of the lids. After two weeks the left eye was clean and well, with smears negative, but smears from the right eye were still positive, though the cornea had healed, the eyeball was white, and only a small incarceration of the iris was present. The rapid healing of this eye was the most remarkable incident in the whole series of cases.

Case VII.—Ethel C., 1 month old. Both eyes red and much pus; not so much swelling of the lids. Daily injections of gonococcus phylacogen, ½ to 1 c.c., were given. After the second day the eye appeared almost well, eyeballs white. After the first week the eyes were white and conjunctiva of the lids were pink. Smears were negative after ten days.

Case VIII.—Thomas P., 10 days old. Treated six weeks in the ward with argyrol and boric acid. The eyes were not swollen and there was only a small amount of discharge, but smears showed gonococci still present. Two doses of 1 c.c. of phylacogen were then given subcutaneously, following which the smears were negative and the patient was discharged.

Case IX.—Wm. G., 1½ years old. Eyes sore and discharging for ten days. Both were swollen and closed and there was much discharge. Cornea clear. Five doses of gonococcus phylacogen 1 c.c. were given subcutaneously. Reaction was somewhat marked, temperature 102°. After five days the eyes looked entirely well and normal and patient is ready to leave the ward.

Analyzing the preceding cases, the use of the vaccine seems to be warranted in this disease, as the reduction of the swelling of the lids is so prompt and the deeper tissue of the cornea and conjunctiva seem to be protected quite effectively against the invasion of the gonococci, as shown by the cases in which there were abrasions of the cornea.

This appears to be a useful adjunct treatment, especially in those cases which cannot be treated in a hospital or have proper nursing facilities, as in the smaller places in the country. The vaccines used were stock vaccines of three different laboratories and were purchased in the open market. Fifty million gonococci as an initial dose and one hundred million as subsequent doses did not affect even small babies in any untoward manner locally or systematically, and double this dose was used for adults and was well borne. The use of the gonococcus phylacogen, a strained vaccine, was attended by a more rapid effect, but the chill and rise of temperature, as reaction, make its use outside of a hospital, or where no trained attendance is at hand, rather alarming to the lay mind, though expected by the physician; it might be used to advantage in a case of emergency when the eye seems threatened and an immediate effect is desired, but the active immunity established by the vaccine seems more desirable for the ordinary case. These cases were treated alongside of other cases in the ward in which the old treatment alone was used, and many of the latter ran a course of six to eight weeks, during which the swelling and discharge persisted for a long time, with the attendant worry as to the danger of complication of the cornea and loss of the eye.

In not one case treated was the result at all unsatisfactory and the almost immediate reduction of the inflammation was most gratifying.

The use of the vaccine alone does not seem to be justified, but should be supplemented by measures of local cleanliness and antisepsis.

140 Madison Ave.

## THORIUM X IN THE TREATMENT OF PERNICIOUS ANEMIA, WITH REPORT OF CASE.

By FRANCIS E. PARK, M.D.,

STONEHAM, MASS.

Among all the advances and discoveries of modern medicine, there is none so interesting and marvelous as that which relates to the action and properties of the radioactive elements. A great literature has already been built about radium and its achievements, but so far very little has been published in this country about thorium, the sister element.

Discovered in 1828, by Berzelius, in the magnetic ores of Norway, it is found combined with monozite, orangite, thorite, and other rare minerals containing the cerium group. Named in honor of the Thunder God, it was given the symbol Th. and found to have an atomic weight of 232.63 and a specific gravity of 10.96.

When isolated it is a grayish powder, which assumes an iron gray luster when burnished. Heated in the open air it burns readily with a brilliant flame, forming thorium dioxide. Of late years it has been used in the arts very sparingly, owing to its great rarity and cost, but it was not until 1898, when the discovery was simultaneously made by Mme. Curie and Professor Schmidt of the radioactivity of its salts that it was thought of as a possible therapeutic agent.

In 1902 Rutherford found that there were given off from its salts emanations similar to those of radium, which could be blown from one vessel to another, and which would render radioactive the walls of the container. Since that time, owing to the painstaking researches of Bickel, King, Plesch, Gudgent, Czerny, Canne, Curie, and others, much very interesting information has been gained.

Regarding the length of its existence, science tells us that thorium exists for millions of years in an unchanged state, constantly giving off energy. From the element thorium is derived mesothorium, which exists 7.9 years. The next step is mesothorium 2, with a life of 8.9 years. Then in order, radiothorium, 2.9 years; thorium X, 5.25 days; emanation, 76 seconds; emanation A, 15.3 seconds; B, 79 seconds; C, 1 second; D, 4.5 minutes.

Investigation has shown that of these various products of thorium, X has the most wonderful properties and is of practical use in internal medicine. Thorium X is produced by superimposing upon a layer of radiothorium a solution of 1-3000 of sodium chloride. By using definite quantities of each, an absolute strength of thorium X is obtained, which can be measured by a delicate electroscope, and is expressed in Mache units.

Careful experiments have demonstrated that this substance in large doses is inhibitive to cellular life. Seeds, soaked in strong solutions, lose their power to grow; and dogs fed with doses of several million Mache units die, and on examination present necrotic areas in the gastrointestinal tract. Epithelial cells of cancer, and of lupus are influenced as by radium. There has been one fatality in the clinic of Gudzent, where a fat woman of fifty-nine years of age was given intravenously 900,000 M. units on March 21, 550,000 more March 30, April 2, 10,000 of thorium A, April 6, 3,000,000 M. units; went home April 10 apparently in good health. Returned April 15 suffering with pain in the abdomen; leucocytes, 312. April 18 developed hematemesis and melena. Leucocytes dropped to 100. Death occurred, and at autopsy the same signs were found as in the cases of dogs killed by thorium. In the same clinic other patients had received as high as 4,000,000 M. units without harm.

Given in moderate doses no harmful effect has ever been observed, either upon the epithelium of the gastrointestinal tract or upon any of its secretions. Likewise there has been no deterring effect noted from its action upon the kidneys.

The observed fact that after twenty-four hours the greater part of the thorium X that had been given to dogs could be recovered from the red marrow of the bones, directed the attention of investigators to its action upon the blood. Then it was found that there was a remarkable stimulation exercised upon the red cell formation. This discovery was eventually made use of by A. Bickel, professor of internal medicine at the University of Berlin. His case as he related it to me was most interesting.

The patient, a man of middle age, had had pernicious anemia for several years, had apparently reached the end, and was about to die. There was an enormous amount of anasarca. The red cells numbered 960,000. Small doses of thorium X were given by the mouth three times a day, with the following results as regards the number of red cells: May 1, 960,000; May 10, 1,200,000; May 20, 2,085,000; May 30, 4,320,000; June 12, 4,600,000. This patient received 50,000 M. units daily during this period. He became apparently perfectly well, and the blood picture became and has remained to the present time normal. Dr. Bickel said that the improvement was almost startling, and in no way simulated that seen in the usual recovery that follows the earlier relapses.

Plech reports a case from Kraus's clinic where in a case of pernicious anemia with a red count as low as 340,000 in a woman of thirty years there was an increase of 860,000 red cells in twenty-four hours. This patient also made a speedy and so far a permanent recovery.

Up to last September there had been nine cases treated by this method. Three of these showed no effect, and probably were cases of so-called secondary pernicious anemia, for in such cases it has been observed that thorium X has no effect. The other six cases responded in the same manner as did that of Bickel's, and are apparently cured.

In the fall of 1912 Dr. Bickel was summoned in consulation to see a case of pernicious anemia in Greenwich, Conn. This lady was at the point of death, suffering from a complication of heart and kidney disease as well, and survived but a few weeks. In spite of the unfavorable circumstances, however, her red cells increased in that short time 800,000. Having a case that was getting worse rapidly, I was fortunate in being able, through the kindness of Dr. Bickel, to obtain the specimen of radiothorium which he had brought with him for use, in my own case. This case I will now report, and I believe I may claim the honor of reporting the first case of pernicious anemia cured in this country by the use of thorium X.

Professor B., forty years of age. Father died of prostatic trouble and had had a cough for many years. Mother died of tuberculosis pulmonalis. He has one brother who is in good health. The previous history up to the time of his present disease is negative save for a severe attack of yellow fever in 1888. He fully recovered from this and for many years has led an athletic life. While teaching at college in 1906 his health began to fail, and in May of 1897 he consulted an eminent hematologist of the University of Michigan and was told that he had pernicious anemia. He improved under arsenic and went along for nearly a year, when he had another relapse. Again the arsenic was of service although he was longer getting back onto his feet, in fact he did not get entirely back this time, but kept along fairly well until in 1908 he had a very severe relapse. After about four months he got about again and from that time, save for an attack of pneumonia in 1909, he did very well up to the early fall of 1912.

About this time a bad relapse started, and although the old remedies that had formerly checked the progress of such an attack were faithfully used, he steadily failed, until things began to look very serious. At this time I obtained my thorium and began treatment with it. During the first three weeks I combined with it an electric treatment of the long bones and solar plexus, which had given such good results in the treatment of the case since 1908, that I was very loth to discontinue it. He continued to fail steadily and it occurred to me that possibly the electricity was in some way rendering inert the thorium emanations, so this was stopped. At once he began to gain in a very decided manner. His condition at that time was as follows: Edema of all the dependent parts, dyspnea upon the slightest exertion, poor appetite and feeble digestion, and a blood count of 1,200,000 red corpuscles. In just four weeks from that time he was walking about town as vigorous as ever; edema entirely gone, fine appetite and digestion, and a blood count of 4,800,000 red cells. One week later

the count went to 5,280,000; the blood picture was normal and the patient volunteered the statement that he had not felt so well for seven years. As a test of his heart action he recently climbed a long hill, with a snowstorm in progress, without getting out of breath.

Of course many years must elapse before we can positively say that such a case is entirely cured. But the return to normal of the cells in shape as well as quantity leads me to feel very optimistic. In his case the remedy was given almost entirely by the vein, 20,000 M. units being injected with an all-glass syringe and a 27-gauge needle, into the median basilic every other day. No irritation was felt. At first a few injections were made into the muscles but as this caused considerable soreness it was discontinued. A recent communication from Dr. Bickel advises me that in his opinion it is best to give an intravenous dose of 50,000 M. units once every four days until three have been given, and then to continue the treatment with a daily portion by the mouth of 20,000 units, one-third to be taken after each meal.

Whether thorium X proves to be a specific cure or not for pernicious anemia the evidence seems to be irrefutable that in it we have the most potent remedy to aid that is yet known to medical science.

## THE RATIONALE OF THE USE OF ADRENALIN IN THE TREATMENT OF ASTHMA.

By CAREY P. McCORD, M.D.,

DETROIT, MICH.

In the treatment of asthmatics the neurotic and personal elements give occasion to so complex an etiology that prophylaxis is only feasible after a study of the vagaries of the individual patient. In the intervals between attacks so free from symptoms is the patient that the treatment at this period is again essentially prophylactic and embraces the removal of any predisposing conditions, and a general hygienic systematization—all in an effort to ward off the attack, or at least to lengthen the intervals between paroxysms. The forte for drug therapeutics would then appear to be in the relieving of the distress of the attack. The position occupied by adrenalin in this condition is peculiar in that although in the majority of cases it is astonishingly effective, it has attained to but scant use at the hands of the general practitioner. It is upon this value of adrenalin, together with its exemption from any permanent secondary effects, that this paper is based, drawing freely upon results obtained by various clinical and experimental workers.

The immediate pathological conditions exciting the symptoms of the attack has given rise to numerous theories. The most plausible and the one at the present time most substantiated by experimental work is that which ascribes the paroxysm to spasm of the circular muscle coat of the bronchial wall. Secondarily congestive swelling with exudation into the bronchial cavity occurs in many cases, and the spasm of the bronchial wall is probably aggravated by the distention of the distal air sacs, pressing upon and further constricting the bronchioles. That such a bronchial spasm may account effectively for the symptom complex produced in asthma has been shown by Brodie and Dixon.[1] They demonstrated that the vagus is the only motor nerve to the bronchial musculature and that in this nerve run dilator and constrictor fibers for the bronchial muscles. Constriction of the bronchioles could be induced by stimulating the constrictor fibers with muscarine, pilocarpine, or electricity, whereupon there occurred all the signs and symptoms characteristic of bronchial asthma. Removal of the constricting influence arrested at once the attack, only to reappear when the constricting influence was re-exerted.

Januschke and Pollak[2] in 1911, after having obtained the experimental bronchial constriction in a manner similar to Brodie and Dixon, demonstrated a dilatation after the intravenous administration of adrenalin. Jackson[3] in 1912 described a series of experimental studies in which the action of adrenalin was investigated. He obtained dilatation of the bronchioles on adrenalin administration, which he concludes is due to stimulation of the bronchodilator fiber endings from the vagus. Jackson indicated further that all his results bear out the opinion that in the intact animal one of the functions of the adrenal glands is to assist by means of their internal secretion in counteracting pathological processes or products, which tend to produce an abnormal broncho constriction. An additional factor in the bronchiole dilatation lies in the observation of Elliott[4] that the administration of adrenalin stimulates a discharge of adrenalin from the adrenal glands, which becomes available for dilatation of the bronchioles. From this group of experimental studies it would appear reasonably well established that adrenalin dilates the bronchial musculature.

The striking clinical results, although explained through many theories, probably owe their beneficial action, at least in part, to this phenomenon. In 1900 Solis-Cohen[5] suggested the use of adrenal extracts in certain forms of asthma associated with vasomotor ataxia on the supposition that asthma was caused by obstruction of the respiratory passages by irregular swelling of the bronchial mucosa similar to angioneurotic edema, and that adrenal extracts by increasing the vascular tone prevented and relieved such attacks.

Lermann,[6] in connection with his employing adrenalin in asthma, has made a study of blood pressure. Before and after the subcutaneous administration of adrenalin, blood pressure measurements were made. He states that the blood pressure which is not high in asthmatic attacks is not increased by hypodermic injections of adrenalin. He attributes the beneficial action of adrenalin to its relaxing the bronchial spasm.

Reilly[7] advocates the use of adrenalin. However, in his cases the asthma was ascribed to nasal pathology and adrenalin was used as a spray upon the contact surfaces with a view to relieving the edematous condition. Eminently satisfactory results were obtained. The inhalation of some adrenalin is a probability in such treatment so that the satisfactory results may have been obtained in a way similar to Segel,[8] who, by causing inhalation of adrenalin in oxygen obtained more than transient relief. However, his small number of cases precludes anything more than hopeful possibilities. Equally hopeful results were obtained by Mathews[9] by spraying the nose with adrenalin in acute asthma. Since only a portion of his series had any nasal defect, the spraying of the nose with so much relief lends plausibility to the possibility that inhalation of adrenalin leads to bronchial dilatation.

Freudenthal[10] advocates the endobronchial appli-

cation of adrenalin for treatment of asthma and cites a series of cases so treated.

Weiss[11] is enthusiastic over results obtained from 3,000 treatments of mild and severe asthmatic cases. His cases obtained permanent relief, and all except ten from a single injection. He supposes that any stimulus contracting the bronchial musculature must follow a nervous condition, or is due to some fault in the composition of the blood, this latter depending on the condition of the blood-forming organs, on the sufficient exchange from the lungs and the skin, on the proper excreting function, and upon the balanced action of the organs of internal secretion. Weiss is of the opinion that through disturbed gland action, the circulation is impaired and carbon dioxide accumulates, which in turn brings on the bronchial attack. He used in treatment sterile watery solution of adrenalin in combination with pituitary extract. This he injects subcutaneously. This writer is of the opinion that adrenalin alone will not suffice. No deleterious actions followed the use of the drug in this way. The idea is advanced that since the attack is caused by faulty blood composition the relief following the administration of the drugs is due to the correction of the circulatory disturbance.

Ephriam[12] reported results obtained in his own hands and made a study of results of other workers. Adrenalin treatment, according to this writer, was introduced into Europe by v. Jagic[13] and later was used by Hofbauer.[14] Of his own cases he writes, "I, too, had opportunity to convince myself often that the subcutaneous injection of .75 to 1 c.c. of the marketable 1 per cent. adrenalin solution, almost invariably terminates a severe asthmatic attack." Ephriam further calls attention to Kauert's[15] observation that the site of injection has somewhat to do with the effect of the drug. Injections in the thoracic region react more intensively than those in the more remote portions of the body. Recommendation is made that injections be made in the forearm. The beneficial action of adrenalin given subcutaneously is very transient. In patients who suffer from rare, short attacks, the interval seems in no wise altered even though pronounced relief is given at the time of the paroxysm. In cases of severe protracted *status asthmaticus* the adrenalin effect never lasted more than two hours. However, no ill results were encountered from a large number of injections at two-hour intervals. Ephriam watched the effect of subcutaneous administration of adrenalin, with the bronchoscope. Anesthesia of the mucosa was carried out as follows: larynx with 20 per cent. alypin, trachea and bronchi with 10 per cent. novocain. Such an anesthesia occurs without producing anemia of the bronchi mucosa. With the bronchoscope in place 1 mg. adrenalin was injected into the back and observations were made. In the cases with severe hyperemia an unmistakable paling occurred after 25-60 seconds. From these observations Ephriam concurs in the theory advanced by v. Jagic and Minkowski[16] concerning the production of bloodlessness in the bronchial mucosa upon adrenalin administration. In addition to the spastic process, hyperemia, swelling, and hypersecretion of the bronchioles play important additional causative parts in asthma so that the characteristic ventilation disturbances of the lung result. If, then, as a result of the subcutaneous adrenalin injection, paling of bronchial mucous membranes and extension of the bronchial lumina both occur, not only does normal lung ventilation return, but also the expectoration of the retained secretion becomes possible—all factors of relief. Ephriam, in order to permit the adrenalin to act upon the bronchial mocous membranes more intensively and extensively than is possible from subcutaneous injections, applies the adrenalin endobronchially. This he finds much more effective toward relieving the hyperemia and swelling, and the duration is much more lasting, being up to ten hours in cases cited by Möller.[17] Such results follow the bronchoscopic observations which permit only examination of the large bronchi, so that the relaxing action of adrenalin on the bronchioles cannot be studied in this way.

Another point of more than passing interest is to be found in Ephriam's article in connection with the eosinophilia occurring synchronously with the asthmatic attack. In four asthmatic patients treated with adrenalin the blood was examined before and after treatment with reference to eosinophilia. Very regularly the adrenalin administration was followed by a pronounced diminution of the eosinophiles, in part a reduction from 10 per cent. to 3 per cent., but continued study indicated that in these patients the eosinophilia varied greatly. Whether the decrease was due to the adrenalin *per se*, or was concomitant to the changes connected with the asthmatic symptoms is left in question.

In the above abstracts no attempt is made to cover the entire literature, but rather to cite the experimental basis for adrenalin treatment and attempt to correlate clinical results, explained at present by means of "far-fetched" theories. That adrenalin has found so scant favor at the hands of the general practitioner may be ascribed to the fear of evil secondary effects. Braun[18] warns against the subcutaneous injection of adrenalin, but widespread and extensive clinical experience not only does not bear this out, but indicate that such a fear is groundless. Kirchheim[19] injected daily 12 c.c. of the market solution for many weeks into patients with severe infectious diseases. No secondary effects of evil nature were to be noticed. At the time of injection certain unpleasant results have been pointed out as occurring transiently. Severe palpitation of the heart may occur, which leads to a very pronounced, but not accelerated pulse. A peculiar restlessness may set in which may create the patient's alarm, and at times the face may rapidly become very pale, but all of these pass rapidly away and at the same time the respiration becomes easier and softer and the rattling and wheezing sounds cease.

From the results indicated above growing out of the use of adrenalin by both laboratory and clinical workers it seems reasonable to conclude:

1. Adrenalin extends the lumina of contracted bronchioles.

2. This dilatation of the bronchioles is probably the basis for the beneficial action of adrenalin in the treatment of asthma.

3. The dilatation follows subcutaneous, intravenous, and endobronchial administrations.

4. The action is transient but very effective in relieving the acute attack. The subcutaneous administration apparently is the most transient.

5. The administration is simple and no injurious results follow as a secondary sequence.

# A STUDY OF FOURTEEN CASES OF ALCOHOLISM IN CHILDREN APPARENTLY FREE FROM MORBID HEREDITY.*

By ALFRED GORDON, M.D.,

PHILADELPHIA.

NEUROLOGIST TO MOUNT SINAI, NORTHWESTERN-GENERAL AND DOUGLASS MEMORIAL HOSPITALS.

The eminent French moralist, pedagogue, and philosopher, Jean Jacques Rousseau, has portrayed in his immortal works, "Emile" and the "Treatise on Education" the nature and the gradual development of the morality and intellectuality in children. He admits that an infant comes into the world with best instincts and only improper directions in his bringing up, as well as examples of bad surroundings, render him apt to commit errors in life and to become undesirable. This thought, while correct in many respects, is deficient in others. It is true that a child is apt to acquire whatever he comes in contact with and whatever he is taught, provided his cerebrum is intact. But one must not forget that each individual possesses certain inherited peculiarities and tendencies which he carries with him through his entire life.

Rousseau's ideas are in accord with our modern conception concerning various influences in the development of the child. We know that the hereditary factors *per se* are not sufficient to create mental abnormalities. Environmental influences play, speaking generally, a very important rôle. It is a well known fact that species of the animal kingdom undergo evolution and transformation under the influence of the exigencies of the environment. While heredity and environment determine all our physiological, anatomical, and psychological characteristics, nevertheless, environment plays a more preponderating rôle, it corrects and modifies hereditary tendencies. A child can justly be considered as a virgin soil on which everything grows with an extraordinary facility. The mnemonic faculty particularly possesses a surprising activity and with it he possesses an instinctive desire for learning and knowing everything, also a curiosity which cannot be stopped. Intelligence, sense of propriety, faculty of adaptation are all rudimentary. From many standpoints he could be compared to an animal. Like the latter, he is attracted only by things that appeal to his tastes. As reasoning power is rudimentary, impulses cannot yet be controlled. The child is very anxious to possess what appeals to him and displays violent anger when his desire is not promptly satisfied; he does not know obstacles. Education, proper bringing up succeed in controlling and inhibiting all sorts of desires and tendencies. But when these factors are wanting, a free hand is given to any desire and tendency to develop in a direction which is most acceptable to the child. Another feature characteristic of the child's nature is imitation. It is very pronounced at a tender age. Easily suggestible, children are always anxious and inclined to do, to act, and to behave like adults. In this manner they are apt to succumb to outside influences which may lead them to the most extraordinary acts. There are imitations of acts which may be the result of noble sentiments but there are also imitations which may lead to and end in criminal acts. In view of the imitative faculty being the strongest in the child's nature, it is extremely important to place him at the earliest possible period of his life in a milieu which will be conducive to an imitation of the noblest sentiments that a human being possesses.

Among the various obnoxious influences which, when taken up by children, are developed by them into a habit with the greatest facility is alcoholism. It has been my good fortune to observe and study a series of fourteen cases of alcoholism in children in the most systematic way. This study has demonstrated to me the disastrous effect of this poison on the physical growth, and on the development of mental faculties and moral conceptions. Moreover, this study is especially useful, in my opinion, in view of the fact that all my fourteen subjects are individuals apparently free from any morbid hereditary transmission, as a very careful investigation revealed unusually healthy ancestors possessing a marked longevity. In this manner the effect of alcoholism is most evident, as morbid hereditary influence played here no rôle whatever.

Nine of the entire series of children became orphans at a very tender age. Distant relatives took charge of them for a certain time, but soon abandoned them and those children were placed indiscriminately with various families for menial services. These families happened to be of a low moral and intellectual level. Promiscuous relations between various members of the same families from the standpoint of acquired habits and sexuality had undoubtedly the most unfavorable influence upon those children. They grew up without any supervision or direction and became early the victims of the bad habits which they witnessed daily. Drink was the most conspicuous vice that they saw being cultivated. At that time their ages ranged between eight and fourteen years. In presence of surroundings of such a nature and being deprived of any wholesome outside influence or example, a child, whose chief characteristic is to imitate, will *nolens volens* succumb to what is frequently repeated before him and acquire of necessity the craving and anxiety for all bad habits. Such was the case with the first nine children of my series. They soon acquired the habit of drink. At first there was only a tasting of beverages, gradually a distinct alcoholic craving developed. Several of them soon abandoned their so-called benefactors and gave them-

*Read at the meeting of the American Society for the Study of Alcohol and Other Narcotics, held in Washington, December 10-11, 1912.

selves to vagabondage. In order to support themselves they committed thefts, and most of their meager illegitimate acquisition was devoted to the use of drink. It is needless to say that other vicious habits followed and then accompanied the use of alcohol. It is also needless to enumerate the number of escapades and of various unlawful acts committed by these juvenile degenerates. Here the degeneracy was not to be considered as an inherited abnormality due either to some prenatal cause or to a congenital transmission of some atavistic characteristic, but as an exclusively acquired vicious tendency due to environmental factors which began to direct the impressionable human nature at a tender age. A number of times they appeared in various cities before judicial officers. The juvenile courts heard their vagaries and small crimes recited a number of times. What is particularly interesting and important is the mental status and the medical histories of these nine juvenile unfortunates. Epileptic convulsions figured in five of them. Various neurotic phenomena, such as tremors, twitchings, restlessness, acquired mimicry, insomnia were evident in all of them. Pallor of the face, gastrointestinal disturbances of a pronounced character, tachycardia are the other somatic manifestations. The mentality was low. Some of them were incapable of appreciating their condition when the latter was explained to them in the simplest possible way. Some of them were brutal and without the least idea of altruistic sentiments. Others presented a marked mental habitude in the intervals between the attacks of alcoholic debauchery. A tendency to attack and injure was present in all of them. One individual developed a penchant for killing chickens and he did it very frequently; he would take special trips to farms and steal chickens for the purpose of enjoying the act of killing. Pederasty was also observed in one of them. All were averred masturbators. The moral conception was rudimentary and in some of them actually nil. None of them expressed any desire for work. Prison, vacant lots, country farms, unoccupied buildings—these were the habitats of these unfortunate victims of early alcoholism. It was impossible to determine the amount of the alcoholic beverages consumed by them. Such was the mental and physical picture of nine of my fourteen individuals at the last examination four months ago. Their ages ranged between fourteen and nineteen.

The remaining five members of my series lived under the supervision of their parents from early infancy until the age of puberty. During that time the parents suffered various financial shocks of the gravest nature. They could not or would not face gravely the calamity and commence life anew in other directions. Other domestic circumstances of the most unfortunate nature, such as marital infidelity, etc., added considerably to the material disaster. Thus was created an open avenue for the reception of the ever-present vice—alcoholism. The homes were broken up, the children drifted away, joined one or another parent or a relative. From that time on the children's fate was decided. As they were of a tender age, from four to seven, they became involuntary witnesses of the physiological and psychological misery. Beer and wine were given the children, at first occasionally, later more frequently. Gradually they acquired a desire for beverages and the latter became an unavoidable element in the house. The fathers and the mothers gradually sank lower and lower, the children were sent out on the street to beg and were compelled to bring to their parents the collected money which was partly spent on drink. In such a milieu the children grew up, partly deprived of necessary food but always supplied with beer which then became a necessity to them. The further development of events is identical with that of the first group of my series.

Mental arrest, mental hebetude, lack of moral conception, perversion of moral sense, no knowledge of the most ordinary normal relationship between man and man, no conception of conventional laws, brutal tendencies and impulses of the most primitive character, abnormal sexual proclivities, excessive use of tobacco—are all manifestations which develop side by side and I must say, because of alcoholism. Not once were they found in a stuporous and confusional state following drink. Some of them had attacks of genuine alcoholic delirium with visual hallucinations.

The picture presented here is drawn from the histories of fourteen individuals followed up for a period of several years. They all present common features, although they may vary in details. These unfortunate victims of acquired alcoholism do not know, and never learned the necessity of working, never understood the meaning of obligations, of altruism, of morality, all factors which distinguish man from animals. Their resemblance to animals in this respect is very striking. Like the latter, they live in accordance with instincts and are entirely controlled by sudden impulses. Voluntary inhibition is not in their domain; it exists in them in the most rudimentary manner. The moral, intellectual, and physical precipice into which they are fallen and in which they are held, was created for them directly by alcoholism and indirectly by unfortunate circumstances. The latter are, undoubtedly, the original cause of physiological disorders as well as of social evils.

Society endeavors to preserve itself from infections and transmissible disease by means of hygienic measures, such as disinfection and isolation of already infected ones. Prophylaxis constitutes now the most rigorous measure, as it destroys the cause of the infection. As an illustration of the importance of preventive medicine one may mention the suppression of the mosquitos in the countries where malaria and yellow fever prevail. In the same manner and with the same vigor the community must endeavor to preserve itself from criminality, delinquence, from feeble mindedness and from other deviations from normal by attacking the cause which produce these abnormalities. To combat social misery and all its consequences is to combat physical and moral deterioration. Preventing them means to prepare generations better equipped to resist depressive influences in life and therefore more apt to receive an intellectual and moral foundation which will transform them. This is a logical conclusion drawn from the application of biological knowledge to social evolution.

The present study is, in my opinion, valuable from a practical standpoint. First of all, it shows with almost mathematical precision the direct nefarious influence of alcohol on an individual during his physiological development. As was mentioned above, there was no apparent element of morbid hereditary which could possibly be transmitted to the offspring and thus produce the mental abnormalities observed in my fourteen patients.

The infancy was normal, the proper surroundings and the proper care were all conducive to normal evolution of the lives of the fourteen individuals. The evident change commenced from the time when the use of alcohol stepped in. The exact future of the fourteen youths cannot be defined. But one fact is certain, that is, they are lost to the community as far as their usefulness is concerned. Moreover, there is a great danger threatening society. That is, the possibility of their marriage or illegitimate sexual relations. They are then likely to procreate and bring into the world weaklings, individuals with an inherited degenerative makeup. Such a state of affairs is dangerous to society as it produces a slow and progressive deterioration not only of the individual, but also of the species; it produces an intellectual and physical sterility of the race with all its social consequences—lowering of the intellectual status and qualitative depopulation.

## THE NECESSITY OF EARLY INSTITUTIONAL TREATMENT IN MENTAL AND NERVOUS DISEASES.

By F. H. BARNES, M.D.,

STAMFORD, CONN.

MEDICAL SUPERINTENDENT OF DR. BARNES' SANITARIUM.

Much has been said relative to the treatment of mental and nervous diseases and the necessity of sending patients to the various sanitaria and State Hospitals before a psychosis develops or in its acute stages. Some physicians advise against institutional treatment at the start preferring to send their cases to the country to be taken care of in farm houses or the numerous small hotels; others place their mental and nervous patients in city hotels under the care of a trained nurse. Still others advise sea voyages, railroad journeys, or visits to relatives at some distance. Other medical men go so far as absolutely to prohibit sanitarium or hospital treatment, telling their patients they would grow worse under such environment. The fact remains, however, that many patients are not placed in the various sanatoria and State institutions for the insane in the treatment of their individual disease. As a result many chronic cases are admitted to the various sanatoria and state institutions for the insane each year. The public at large are suspicious of institutions, and this feeling of distrust is one of the hardest propositions that alienists have to combat. The name lunatic or insane asylum should not be used by medical men, but rather should the different State institutions for the treatment of mental disease be designated State Hospitals.

It should be possible for patients suffering from mental disease in the acute stages to commit themselves voluntarily to the various State hospitals and sanatoriums, and psychopathic wards should be established in connection with each one of these. The following is taken from the report of the Superintendent of one of the Connecticut State Hospitals: "I believe that the additions in the number of the insane in state hospitals could be kept below that naturally expected from the State's gain in population were it possible to treat a larger proportion of cases in the incipient stages of their disease. I do not consider it possible to do this as long as practically the same procedure is employed in committing a patient to an insane hospital as is followed at the trial of a criminal. We can not wonder that under present conditions our hospitals are regarded not as hospitals but as custodial institutions and that insanity is regarded not as a disease but as a disgrace that must be concealed as long as possible. The expense of providing a so-called reception hospital, slightly removed from, but under the same management as the state hospital, would not be great, and the necessary changes required in the statutes to permit a patient to repair of his own accord to this hospital or be brought by his friends or relatives with the same freedom as to a general hospital need not be radical. Certain cases would of necessity have to be committed to the hospital in the same manner as at present, but a large number, especially if they were given the alternative, would no doubt, enter the hospital of their own accord or at the solicitation of their relatives. They would thus enter the hospital sufficiently early to receive benefit from the treatment administered and their average stay in the hospital would be much shorter than it is at present. The interests of the patient could be properly safeguarded by a provision that if he were unwilling to remain he could not be detained in the hospital beyond a stated period. If he requested his release and it was deemed unwise by the hospital staff to restore him to liberty, he could be examined at the hospital by two physicians and if found insane on their report could be committed by a Judge of Probate entirely without publicity. The chief advantage of having a detention hospital in connection with the existing state hospitals rather than a detached and independent intitution, would be the ease of transfer from the detention to the main hospital and the lessening of expense incident to erection, administration and maintenance. We have received during the period a number of patients who have voluntarily committed themselves for treatment. The majority of these patients were restored to their normal mental condition and left the institution after a comparatively brief stay."

The following from the report of the Superintendent of one of the large private sanitariums of Connecticut: "Where necessity compels the alternative of hospital care or breaking up the order of the home to provide for one of the members, there is fortunately less reluctance than once existed to employ the former; if, however, the onset of the malady is slow, the fact of mental illness is reluctantly accepted; and unless there are more urgent symptoms than delusions that seem to be harmless, or if there is simply insomnia and incapacity for work, the need for hospital treatment, if considered at all, is thought of only as an expedient to be used when all other means have failed. The individual, who suffers mental disorder, is fortunate if the onset and course of the disease is such as to render hospital treatment imperative early. No greater misfortune, after the fact of the disease itself, can happen to the sufferer from a psychosis than to become a prey and victim of predatory isms and cults that flourish today as never before. Acting on the belief that no harm can result, even if no benefit is derived from such a course, the patient's friends indulge the vain hope that the tottering mental citadel may be propped up by some occult means, suggestion founded on a religious basis, or what not, with the result that an already jaded nervous system is subjected to trials that would tax the forces of a normal person, and when the hospital is finally reached, whatever chances for recovery earlier existed. have been sadly jeopardized. An-

other interesting abstract written by a former hospital superintendent who had many years of experience in the treatment of mental disease. The public mind is becoming more convinced of the importance of committing the insane to remedial treatment of appropriate institutions at an early period of the disease, and of the imminent peril attending the delays which arise either from the morbid hesitancy of friends to meet the emergencies of the case or from a desire to test the efficacy of private treatment, traveling, etc., delays so often fatal in their effects, and which often render nugatory the final resort to the hospital.

"One of the first principles of the treatment of the insane, is to remove them from all those domestic associations which are connected with the origin or the progress of the disease, and from the direction or management of those whom the patient has been accustomed to control, either through natural authority or affection, and to present to them an entire change of scene and of all surrounding influences. We can thus hope to break in upon the morbid train of thought, and remove those diseased imaginations which so greatly distress them."

Mental disease is on the increase and will be until the medical profession realizes the necessity for immediate treatment of the borderland cases. Many people keep their relatives at home for months, and in some cases for years because they have morbid fears that they cannot trust their own flesh and blood to the tender mercy of hospital treatment. This should not be the case; people should have confidence in those who by years of experience nad training are best adapted to care for the mentally deranged. It has been authoritatively stated that if all cases of mental and nervous breakdown were taken to hospitals and treated from their incipiency the number of cure could be increased by 50 per cent. People generally should be enlightened on this subject and taught that institutions for the treatment of mental and nervous disease are based on humane principles and that hundreds of earnest men on the staffs of the various hospitals are working constantly to alleviate suffering in every form and are striving to find out the means best adapted for stamping out the thing which is such a menace to our nation at the present time. This can only be accomplished by the cooperation of the medical profession.

In the fight against the great white plague, we have been conclusively shown how much can be accomplished by united effort. The unlimited number of tuberculosis hospitals being established; the interest of the public brought about by lecture and exhibits and their hearty endorsement of all that is being done is a demonstration of the efficacy of united work by our profession. If mental disease is allowed to increase at the present ratio it will not be many years before the burden of taxation for the care and treatment of these unfortunates will be a heavy one. Of this, we, as taxpayers, must each bear a part. Much can be accomplished by preventive means in this as well as in other lines of disease. It is our duty to teach the public the necessity of early hospital treatment of mental disease and the benefits derived therefrom. Surely there is no better cause to interest us at the present time.

It is self-evident that a regulated life under the supervision of a medical man and assistants trained to care for all forms of mental alienation is far superior to being bundled about on steamships or railroad trains with the unlimited number of annoyances which are ever presented to the traveler. Neurotic patients must have medical treatment from those who understand their nervous tendencies. This cannot be obtained in a country farm house or in a city hotel. Such influences only depress and add to the worries of mental patients. Rest is imperative but not rest alone; the various forms of exercise, baths, electrotherapy, massage, vibratory massage, and numerous other therapeutic measures must be at hand in order to provide proper treatment for these cases. The personality of the physician in charge is helpful; by virtue of his training he must keep the sunny side uppermost and provide a lighter shade to the dark picture ever before the neurasthenic type.

The influence of kindness with firmness brought about by long training and experience does much to overcome morbid fears and suspicious ideas. The constant suggestion that the mental sickness is only temporary; that the patient can rise above it and get well does much toward paving the way toward recovery. In fact, the regulated life, the doing of things on time, the knowledge that they must try to help themselves which is the keynote of institutional treatment goes a long way toward the desired end. Drs. Clouston, Bevan, Lewis, Tanzi, and many other prominent alienists enlarge upon the necessity of a regulated life under medical supervision in the various sanitaria and hospitals for mental and nervous disease. The time has come when the profession must stand together as a unit and educate the laity to the necessity of placing their relatives in a proper environment at the earliest possible moment, in this manner avoiding the results of long delay which are only too apparent in all institutions throughout the land. People generally should know that many so-called abuses of the past do not occur in the light of present knowledge and methods of treatment. The institutions generally are striving to the best of their ability to stem the tide of increasing insanity. This can only be accomplished by the hearty cooperation and united effort of the whole profession.

## Medicolegal Notes.

**Proof of Authority to Practise.**—In an action for compensation for professional services registered in a foreign state, where the services were rendered, the undisputed testimony showed that the plaintiff had complied with the laws of that state as a prerequisite to his right to practice. It was held that the question of whether or not he was authorized to practice should not, therefore, have been submitted to the jury. In the case of any dispute in regard to the matter, the court should inform the jury what is required by the laws of the foreign state, so that they may determine whether or not the plaintiff has complied with them. It was held proper to exclude a copy of the plaintiff's license to practice, his failure to produce the original not being satisfactorily explained, and also the certificate of a county clerk to the effect that the plaintiff had registered his license in the office of that county.—Feingold v. Lefkovitz, Texas Court of Civil Appeals, 147 S. W. 346.

**Osteopath—Regularly Qualified Physician.**—In an action on an insurance policy the defendant was liable provided the osteopath who attended the plaintiff was a "regularly qualified physician" as the policy required. The only limitation imposed upon the attendant by the New York statute under which he became licensed as a doctor of osteopathy was that he was not permitted to administer drugs or to perform surgery with instruments. It was held that he was a "regularly qualified physician" within the meaning of the policy, the term being equivalent to one authorized by law to treat the sick.—Anderson v. National Casualty Co., New York Appellate Division, 135 N. Y. Supp. 889.

## MORTALITY AMONG PHYSICIANS.

DR. JACQUES BERTILLON, chief of the Bureau of Statistics of Paris, has recently completed an elaborate and extremely valuable monograph "On Mortality and Causes of Death by Occupation." Among other occupations which are separately considered is that of physicians, and Bertillon in this comparative study makes use of ten series of tables (4 English tables, 2 Scotch tables, 1 Swiss table, 2 Paris tables, and a table for France). The latter table is, however, of little use as it combines physicians with pharmacists, in spite of the great differences between the two occupations.

The mortality of English physicians, according to the Registrar General's statistics of 1860-61-71, was very high at ages under 34, then more moderate, and only averaged from age 45 to the end of life. The statistics for 1880-82 give a lower mortality rate for ages 25 to 45. Finally, the statistics for 1890-92 and 1900-02 show a rather low mortality at all ages. The two tables for Paris (1885-89 and 1890-99) show a very low mortality among physicians at all ages. Bertillon makes the following comments on these comparative mortality data: Consumption is rare. Bronchitis is rare. Other respiratory diseases are of moderate frequency in England, and the rate is low for Paris. Valvular diseases of the heart are of average frequency in England, but the rate is high in Paris. Other diseases of the circulatory system are of average frequency in England. Diabetes is very frequent among English physicians. Alcoholism is a little above the average among English physicians, while it is rare in Paris. Liver diseases are very frequent in England, while they are of only average frequency in Paris. Diseases of the nervous system are numerous among English physicians, while apoplexy, according to the statistics of Paris, is below the average among French physicians. Suicide is very frequent in England; very rare in Paris. Accidents are somewhat rare in England; they are rare also in Paris. Physicians and surgeons of England have a mortality considerably above the average at all ages (equal to that of quarrymen), which is not surprising when we consider the unhealthfulness of their profession. It is the same in Switzerland. Consumption, however, is not much more common among them than among the general population.

In the absence of any statistics of the causes of death, Bertillon recently attempted to explain as follows the remarkable difference in the mortality of the physicians of England and Paris: "The majority of the English physicians are naturally country doctors, who are required to go long distances often in rigorous weather in small open carriages, which they generally drive themselves; it is not surprising then that their mortality is high. The physicians of Paris lead an entirely different life and are much less exposed to inclement weather." The examination of the causes of death justifies this explanation, however, only to a slight degree for, if the diseases of the respiratory tract are very rare among the doctors of Paris they are of only moderate frequency among English doctors. When the mortality of the physicians of England and of Paris is compared, cause by cause, we find that the difference appears to hinge particularly upon the frequency of hepatic disorders, diseases of the nervous system, suicide, in a word, upon the diseases which are related to alcoholism, and it would be interesting to know whether or not the greater use of spirits, in moderation or in immoderation, in England may be the cause which underlies the difference in the two mortalities. A comparative study of the mortality among London physicians, rather than those of all England, and the physicians of Paris would have been fairer and more interesting.

## THE DISTRIBUTION OF ENDEMIC GOITER.

ENDEMIC goiter prevails in certain countries and districts to an extent almost incredible to an inhabitant of this continent. In parts of Europe, chiefly in mountainous districts, the disease is so common as hardly to excite comment. In the Milroy Lectures on the etiology of goiter (*Lancet*, January 18, 1913), Major Robert McCarrison of the Indian Medical Service gives some interesting figures regarding the distribution of the malady. For instance, Ballarger has estimated that about the year 1874 there were in France alone no less than 500,000 goitrous individuals, and 122,700 cretins and cretinous idiots. In Switzerland during the six years between 1875 and 1881, 12,227 young men were exempted from military service on account of goiter. In Italy 3 per cent. of the conscripts were rejected for the same reasons between the years 1859 and 1864. In the provinces of Piedmont, Lombardy, and Venice there were in the year 1883, 128,730 goitrous and 12,885 cretinous individuals in a population of nine and one-half millions. In the Himalayan regions where McCarrison carried on his researches, the disease is so common that in some villages it is difficult to find a man, woman, or child not suffering from the deformity. McCarrison estimates that in Himalayan India and in Europe there are about 5,000,000 sufferers from goiter.

With regard to distribution, two main facts are pointed out, the very marked association of goiter with regions of high mountains and the comparative limitation of the disease to temperate and subtropical zones. The association of the disease with

mountainous districts is so well-known a feature that little comment on this phase of the complaint is needful. But it is worthy of notice that some mountainous countries are practically exempt from goiter, as, for instance, certain parts of Norway and the highlands of Scotland, where it is almost unknown. The disease is not unknown in this country, but for the most part on this continent it is more conspicuous by its absence than by its presence. It is found to some extent in the plains of the St. Lawrence in Canada and in the Hudson Bay Territory.

Although endemic goiter is most frequently met with in temperate and subtropical zones, it is not entirely confined to these regions, for it occurs in Siberia, in Finland, and as just mentioned, in the Hudson Bay Territory. Moreover, regions of great heat contain sufferers from goiter, as tropical South America, Borneo, Sumatra, Java, and India. Temperate and subtropical climates favor most its development, but it will and does occur in any climate. A study of the matter has shown that while the disease exhibits a decided preference for mountainous localities and prevails with the greatest intensity in the deep-cut narrow valleys which intersect the mountain ranges of temperate and subtropical zones, it may prevail in any country, flat or hilly, hot or cold, dark and dismal or bright and sunny, where man cultivates the soil. Consequently it cannot be held that configuration of the soil, rarity of the atmosphere, cold or dry air, or any kind of air exerts a preponderating causal influence.

## THE LACK OF RELIABLE STATISTICS IN THE UNITED STATES.

We are apt in this country to plume ourselves upon being in the van of progress in all respects, but in the matter of statistics we must confess to a marked inferiority to the countries of Europe. In France, in Germany, and in England statistics bearing upon public health or upon social or economic questions are more carefully compiled than here. France is notorious for the minute and painstaking manner in which statistics are kept; it has become a fine art and is not infrequently carried to excess. Everyone is aware of the paternal solicitude exercised over its people by the German government, and it has been said even that bureaucracy is there gone mad. In Great Britain, although the attention paid to gathering statistics is less apparent than in the aforenamed lands, statistics are collected on a large scale and put by for future reference. Indeed, complaint is made that the amount of statistical information demanded under the new insurance law is so great that the physician has no time to give to the diagnosis and treatment of his cases.

All branches of statistics relating to public health, directly or indirectly, have been considerably neglected in the United States. There are no population mortality tables of much value, and it was not until the census of 1900 that any really forward steps were taken toward deriving and tabulating such tables. Now, as a result of the establishment of a permanent Bureau of the Census, the registration of deaths has been placed upon a better footing, but Congress has always nullified to some extent the efforts made to provide an efficient system of death registration by cutting down the necessary appropriations.

Again, criminal statistics are weak and faulty. According to Mr. John Koren of Boston, who read a paper on the subject at the recent International Congress of Hygiene and Demography at Washington, the general purposes of criminal statistics are to furnish: (1) A measurement of the volume of crime during a given period; (2) the facts in regard to kinds of criminality, the classes of criminals, and the methods of disposing of them; and (3) a basis for intensive study of specific criminal problems. Under the present system adequate or partially satisfactory criminal statistics are impossible. To give one example out of many, in order to show the hopeless muddle in which the matter of criminal statistics here is enmeshed, each State has its own criminal code and works under a system of criminal courts unlike that of other States. Of course, the collecting and compiling of such statistics is a task that the federal government should undertake, but the relation of the several States to the national government renders this impossible. There is almost exactly the same difficulty regarding vital statistics. Each State is sovereign, to a great extent, as to its methods of dealing with these statistics. Marriage statistics also have received but scant attention here and national registration of marriage has, of course, never been established in the United States. Outside of the District of Columbia and the territories the national government has never attempted to assume the task of regulating in any way the institution of marriage. Statistics relating to marriage or divorce are comparatively valueless. It is very important that vital statistics at any rate should be full and accurate, and it is a distinct slur on a country like this which is often boastful of its superiority to Europe that a small country like Sweden should have systems of vital and criminal statistics immeasurably better than ours. Statistics of all kinds, vital, criminal, marriage, and divorce are factors of no small account in the progress and well being of a country, and it is time that the United States followed the lead of European countries, placing everything relating to public health outside the withering blight of politics, and inaugurated a system of statistics suited to its peculiarities of government.

## An Ill-Advised Visitor.

In the interests of fair play, to say nothing of science and of the fate of the consumptive, it is to be hoped that the events of the first week of Dr. Friedrich Franz Friedmann's residence in New York will not prejudice the profession in America against the remedy for tuberculosis which he claims to have discovered. His course since landing here has unfortunately strengthened the impression which the reports of his actions in Berlin had aroused, that his thoughts are occupied with

the commercial aspects of his culture fully as much as with the blessing it will bring to the consumptive and the fame it will bring to himself. The loud trumpeting with which the newspapers greeted his arrival was presumably through no fault of his, but his actions after arrival have not been such as to prejudice the local profession in his favor. It is not the accepted way of proving the therapeutic efficacy of a drug to hire an expensive office on the most fashionable and public street in the city and to announce that patients will be received and treated, for pay, with the remedy, the nature and mode of preparation of which are kept secret. Fortunately, there is a medical practice law, of which Dr. Friedmann's advisers were apparently ignorant, designed to prevent just such practices as this, and it has been impressed upon this gentleman by the officers of the County Medical Society that unless he can prove his case in a proper way, he will not be allowed to exploit his remedy in this city. He may be assured, however, that if he can prove to the satisfaction of his American colleagues that his culture will cure tuberculosis, and if he will reveal the secret of its nature and mode of preparation, none will begrudge him the fame and fortune that await the discoverer of a cure for this disease.

### Bad Teeth and Disease.

It is interesting to read in medical journals of the present time the accounts given by medical men of the close relationship between a bad condition of the mouth and teeth and ill health. It is only within a comparatively recent period that the fact has been generally recognized that the state of the mouth and teeth has an important, nearly an essential bearing on an individual's health. However, now one can hardly look into a medical or even a lay journal without observing that teeth and gums bulk large from a public health standpoint. It might be said without incurring the risk of being dubbed an exaggerator that teeth have become a national issue and that the possession of good teeth is regarded as a national asset of incalculable value. In the *Medical Press and Circular*, January 29, 1913, a correspondent points out that dental disease is much the most common cause of facial neuralgia and facial hemiplasm, while a correspondent of the *Lancet*, February 1, 1913, draws attention to the fact that many cases of ill-health which have been attributed to lead poisoning are not really due to this form of poisoning but mainly if not wholly owing to a foul condition of the mouth. The writer who is a surgeon under the British Factory Acts, argues that if a man's or woman's teeth and mouth are clean, even if they work continuously in a lead factory, there is not much fear of being poisoned by lead, but if their mouths and teeth are in an unclean state there is every probability of them being poisoned. There is no doubt that on the condition of a person's mouth and teeth hinges to a great extent his health. Some may think that undue prominence is being given to the subject of teeth in these days, but if this be so it is certainly a fault on the right side.

### Chemotherapy and Serotherapy.

Not infrequently we hear these two methods of treatment contrasted as if both could not be justifiable; so that one must be destined to drive out the other. We naturally suspect a commercial rivalry beneath arguments of this character. Even if the chemotherapy of a certain disease appears to be ill founded, that should be no argument against this method as a whole, nor are we even warranted in the belief that the future cannot supply what the present moment does not. If the serotherapy of some affection like scarlatina does not inspire our confidence, why should we reject it outright in favor of some other plan of treatment, provided the two are not strictly incompatible? The answer would seem to be self-evident, but the history of therapeutics shows that the apparent success of one plan is not infrequently the death knell of another. It would be better in every way to preserve a semblance of the old treatment as synergistic to the new; and the profession would escape thereby the accusation of fickleness so often made against it. At a recent meeting of the local medical society of Frankfort, Boenke brought up this question in connection with experimental pneumonia (*Berliner klinische Wochenschrift*, February 3, 1913). Serotherapy of pneumococcus infection having been pronounced practically valueless in man and of limited value in the experimental disease—while contrariwise the new chemotherapeutic remedy, ethylhydrocuprein, fails in one case out of three in animals, the author combined both plans in his treatment of induced pneumococcus sepsis. As a result he now saves nearly all his experiment animals and shows incidentally that there are two essential components in the disease.

## News of the Week.

**Civil Service Examinations.**—The New York State Civil Service Commission will hold examinations on March 22, 1913, for the purpose of filling the following positions: Chief medical officer, Health Officer's Department, Port of New York, at a salary of $2,500, open to men only; Dietitian, Health Officer's Department, Port of New York, $900 and maintenance, open to women only; Assistant physician in Iola Sanatorium, West Brighton, Monroe Co., at a salary of $300 to $600 a year, open to men only; and Necrotomist in the office of the Coroner of Onondaga County at a salary of $1,000, open to men only.

**Public Health Service.**—A Board of Medical Officers will meet at the Bureau of the Public Health Service in Washington, on Monday, April 7, 1913, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service. Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and of good moral character. Fur further information or for invitation to appear before the Board of Examiners application should be made to the Surgeon General, Public Health Service, Washington, D. C.

**Dental Interne.**—The United States Civil Service Commission announces an open competitive examination for dental interne, open to men only, on April 2, 1913, for the purpose of filling a vacancy in this position at a salary of $600 per annum and maintenance in the Government Hospital for the Insane, Washington, D. C. As insufficient eligibles were secured from the examination for this position held on December 11, 1912, qualified persons are urged to enter this examination. Application should be made at once to the United States Civil Service Commission for examination Form 1312.

**Miraj Medical School.**—A teacher of physiology,

chemistry, physics, biology, and bacteriology, and preferably with a knowledge of *x*-ray work, is needed in connection with the Presbyterian Mission Hospital Medical School and Leper Asylum at Miraj, India. The hospital has a large and varied service and the equipment is good. A laboratory for teaching purposes is to be erected shortly. Further particulars may be obtained from Mr. Wilbert B. Smith, 600 Lexington Avenue, New York City.

**Prizes of the International Congress.**—On the occasion of the XVIIth International Congress at London next August, three prizes will be awarded: The Prize of Moscow, commemorating the XIIth Congress, of the value of 5,000 francs, will be awarded for work in medicine and hygiene or for eminent services rendered to suffering humanity; the Prize of the XIIIth Congress of Paris, having a value of 4,000 francs, will be bestowed for original work during the past ten years bearing upon medicine, surgery, obstetrics, or the biological sciences in their application to medical science; and the Prize of Hungary, instituted to commemorate the XVIth Congress of 3,000 crowns, will be given for a notable piece of work in medical science which has appeared in the interval since the last Congress. Nominations of candidates for these prizes are invited before June 1, 1913, and should be sent, together with examples of the work on which the candidacy is based, to the "Bureau de la Commission permanente des Congres internationaux de medicine, Hugo de Grootstraat 10, The Hague."

**Medical Faculty of the University of Minnesota.**—The personnel of the new medical faculty of the University of Minnesota, Minneapolis, was announced on February 18 by Dean Wesbrook of the Medical School. The reorganization has resulted in decreasing the force of instructors from 184 to 96, with 24 additional members to be selected from outside, the final number to be 120. Notices have been sent to all the members of the faculty that their resignations, which were submitted in a body to the President to be acted upon at his pleasure, have been accepted. The resignations will take effect on July 31, and the new appointments on the following day. The chief appointments are as follows: Professor of Public Health and Bacteriology and Dean of the Medical School, Dr. F. F. Wesbrook; Professor of Surgery, Dr. James E. Moore; Professor of Obstetrics, Dr. Jennings C. Litzenberg; Associate Professor of Pathology and Acting Director of the Department, Dr. Harold E. Robertson. The heads of the departments of anatomy, physiology, pharmacology, and pathology are still to be selected. The reorganization and the manner in which it has been effected hold out promise of a bright future for the school.

**Chair of Geriatrics.**—Dr. Ignatz L. Nascher of New York has been appointed Professor of Geriatrics in the College of Physicians and Surgeons of Boston, this being the first instance of the establishment of such a chair in any medical school, although lectures on the diseases of old age have been included in the courses of many.

**Röntgen Society.**—The ninth Congress of the German Röntgen Society will be held in Berlin on Sunday, March 30, 1913, directly following the meeting, also in Berlin, of the fourth International Congress for Physiotherapy on March 26 to 29.

**Age Limit for Doctors.**—The managers of the Montreal General Hospital at the ninety-first annual meeting held recently added to the by-laws of the hospital a regulation making compulsory the retirement of the attending physicians upon reaching the age of sixty-two years.

**Medical Schools Approved.**—The New York State Board of Regents on February 20 voted to recognize the following schools of medicine as meeting the requirements of the State: Dartmouth Medical School, Hanover, N. H.; Leland Stanford University College of Medicine, Palo Alto-San Francisco, Cal.; McGill University Medical Faculty, Montreal; College of Physicians and Surgeons, Baltimore.

**District Tuberculosis Hospitals.**—Believing that it is not only desirable but absolutely necessary that the State itself put forth much greater effort looking to the relief of suffering and the prevention of the spread of infection in tuberculosis if the disease is to be overcome, the New York State Board of Charities has recommended the establishment by the State of district hospitals for the treatment of early and curable cases of the disease on the plan of that at Ray Brook. To the local authorities should be left as a general rule the care of patients in the later and less hopeful stages of the disease. Sufficient hospitals should be provided to make possible the separation of the incipient and advanced cases of children and adults and of patients of good moral character from those of the alcoholic type, for instance.

**Resignation of Dr. Kunitzer.**—At a recent meeting of the New York County Medical Society the Comitia Minora reported that in its opinion, although Dr. Kunitzer had been found guilty of the charges against him, yet he had already been sufficiently punished by being deprived of the rights and privileges of the society for the last two years, and that it was therefore willing to accept his resignation without further question. The report of the committee was approved.

**The Plague at Teneriffe.**—Five fatal cases of bubonic plague were reported on February 27, from Teneriffe in the Canary Islands.

**Centenarians Dead.**—At the age of 103 years, William Redmond, a New Jersey farmer, died recently at his home in Oakhurst.

Mrs. Marcelline Leon of Los Angeles, Cal., died on February 27, at the age of 105 years, having been married only a few days previously.

**Deaths in New York City.**—During the week ending February 22, there was a considerable increase in the number of deaths in New York City, as compared with preceding weeks and with the same week of 1912. The total number of deaths was 1,836 with a rate of 17.83 per thousand, while last year there were 1,635 deaths with a rate of 16.49. The increase occurred in all the death groups and from practically all of the principal causes of death. Thus, the deaths from diphtheria and croup were double those reported from these causes in the same period of last year, and there was an increase of 47 deaths from lobar pneumonia, of 35 from organic heart disease, and of 23 from organic kidney disease.

**Diphtheria in School.**—Six cases of diphtheria among pupils of Public School 16 in Wiliamsburg, New York, have made it necessary to close up some of the classrooms.

**Bequests to Charities.**—By the will of the late Hunter Brooke of Philadelphia the sum of $5,000 is bequeathed to the Episcopal Hospital of that city for the endowment of a free bed in memory of the testator's parents; the sum of $1,000 is bequeathed

to the Kensington Hospital for Women, and sums of $500 each to the Philadelphia Home for Incurables, the Home of the Merciful Saviour for Crippled Children, and the Pennsylvania Training School for Feeble-Minded Children.

The Eastern District Hospital and Dispensary of Brooklyn, N. Y., receives a gift of $500 by the will of the late Mr. James S. Bearns of that city.

The Sharon Sanatorium of Sharon, Mass., receives $5,000 under the will of the late Miss Sarah E. Read of Boston.

A bequest of $25,000 is made to the University and Bellevue Hospital Medical College Clinic, New York, by the will of the late Mrs. Maria C. Tailer, in memory of her husband, William H. Tailer. The Home for Incurables, New York, also receives $7,500 in memory of the testator's father, and the New York Orthopedic Hospital receives $5,000.

The Montefiore Home receives $500 and Mt. Sinai Hospital $250 by the will of the late Mrs. Semon Bache of New York.

**Aschoff to Lecture.**—As previously announced, Prof. Aschoff will deliver the Cartwright lectures before the Association of the Alumni of the College of Physicians and Surgeons on March 12 and 15 at the New York Academy of Medcine, at eight-thirty o'clock in the evening.

**Medical Society Election.**—Tri-State Medical Society.—At the annual meeting held in Norfolk, Va., on February 20 to 22, the following officers were elected: *President,* Dr. Southgate Leigh, Norfolk; *Vice-Presidents,* Dr. Stephen Harnsberger, Catlett, Va.; Dr. E. Reid Russell, Asheville, N. C.; and Dr. J. H. Taylor, Columbia, S. C.; *Secretary,* Dr. Rolfe E. Hughes, Laurens, S. C.

Fox River Valley (Wis.) Medical Society.—The following officers were elected at the annual meeting held on February 18: *President,* Dr. F. Gregory Connell, Oshkosh; *Vice-Presidents,* Dr. Wm. Weber Kelly, Green Bay, and Dr. A. T. Nadeau, Marinette; *Secretary-Treasurer,* Dr. R. H. Sweetman, Green Bay.

Bee County (Tex.) Medical Society.—The annual meeting was held at Beeville on February 17, when the following officers were elected: *President,* Dr. Houston Neeley, Beeville; *Vice-President,* Dr. L. E. Parr, Beeville; *Secretary-Treasurer,* Dr. W. E. Sturgis.

**Obituary Notes.** — Dr. Norman Brigham Bailey of Haverstraw, N. Y., a graduate of Yale University, Medical Department, New Haven, in 1871, and a member of the American Medical Association and the New York State and Rockland County Medical Societies, died at his home on February 27, aged 65 years.

Dr. William H. Campbell of Kansas City, Mo., a graduate of Washington University, Medical Department, St. Louis, in 1856, died at his home on February 7, aged 83 years.

Surgeon Henry D. Geddings of the Public Health and Marine Hospital Service, a graduate of the Medical College of the State of South Carolina, Charleston, in 1880, and a member of the American Medical Association and the Medical Society of the District of Columbia, died at his home on February 13, aged 54 years.

Dr. Henry E. Locher of Grand Rapids, Mich., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1877, a member of the Michigan State and Kent County Medical Societies, president of the Board of Health of Grand Rapids, and formerly coroner of Kent County, died at his home on February 9, from Bright's disease, after a long illness, aged 62 years.

Dr. Henry Francis Ballard of Chenoa, Ill., a graduate of the Rush Medical College, Chicago, in 1882, and a member of the American Medical Association and the Illinois State and McLean County Medical Societies, died at St. Francis' Hospital, Peoria, after a short illness, on February 7, aged 60 years.

Dr. John B. L'Hommedieu, First Deputy Health Officer of the Port of New York, and for eighteen years a member of the quarantine staff, died at his home at Rosebank, N. Y., after a brief illness, on February 21, aged 46 years. Dr. L'Hommedieu was born at Medina, N. Y., and was graduated from the New York University Medical College in 1890. After service at the Willard Parker Hospital and the hospital for contagious diseases on North Brother Island, he was appointed to Quarantine, serving as one of the three boarding officers and becoming an authority on yellow fever and other tropical diseases. He was a member of the American Medical Association and the New York State and Richmond County Medical Societies.

Dr. William Conrad Wile, A.M., LL.D., of Danbury, Conn., a graduate of the New York University Medical College in 1870, a member of the Society of Medical Jurisprudence, until recently editor of the *New England Medical Monthly,* and a veteran of the Civil War, died at his home on February 21, aged 66 years.

Dr. William A. Megrath of Loudon, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1886, and a member of the New Hampshire State and Centre District-Merrimack County Medical Societies, died at his home after a short illness on February 12, aged 54 years

Dr. Minot A. Steele of Portsmouth, R. I., a graduate of the Albany Medical College, N. Y., in 1890, a member of the Rhode Island State and Providence District Medical Societies, and medical examiner of the district, died at his home on February 17, from blood poisoning as the result of the bite of a dog, at the age of 45 years.

The Right Hon. Lord Ilkeston, the only member of the medical profession in the English House of Lords, died on January 31, at the age of 72 years. As Dr. Foster and later as Sir Walter Foster, he was for many years professor of anatomy in Queen's College, Birmingham, and professor of medicine in the amalgamated Queen's and Sydenham Colleges. He was one of the founders of the Birmingham Medical Institute, for some time a member of the staff of *The Lancet,* and a member of the General Medical Council. In 1910, he was raised to the peerage with the title of Lord Ilkeston.

Dr. Alexander Mansfield Goodman of Brooklyn, N. Y., a graduate of the New York University Medical College in 1876, died at his home on February 19.

Dr. J. Edgar Ambler of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1893, a member of the American Institute of Homeopathy, the New York State Homeopathic Medical Society, and the Academy of Pathological Science, and laryngologist to the Metropolitan Hospital and assistant surgeon to the Ophthalmic Dispensary, died at his home on February 24, from scarlet fever, aged 41 years.

# Obituary.

## PHILIP HANSON HISS, Jr., M.D.,

NEW YORK.

Dr. Philip Hanson Hiss, Jr., professor of bacteriology in the College of Physicians and Surgeons, Columbia University, New York, died at his home in this city after a long illness on February 27, aged 44 years. Dr. Hiss was born in Baltimore on September 17, 1868, and was graduated from Johns Hopkins University with the degree of A.B. in 1891, and from the College of Physicians and Surgeons, New York, in 1895. The following year he became assistant in bacteriology at the College, under Prof. T. Mitchell Prudden, and also alumni association fellow in pathology. In 1899 he was appointed instructor in bacteriology and hygiene and Alonzo Clark Scholar for that year; in 1903 he was made adjunct professor of bacteriology, and in 1906 a full professor with a seat on the medical faculty of pure science of the University. From 1896 to 1899 he served also as assistant bacteriologist in the Department of Health of New York City.

Dr. Hiss was a member of the American Medical Association, the New York State and Kings County Medical Societies, the Public Health Association, the Society of Experimental Biology and Medicine, the American Association of Pathologists and Bacteriologists, of which he had been vice-president since 1909, the New York Pathological Society, and the Harvey Society. Notable among his research work were his studies on the bacilli of the dysentery group, on the bacteriology of typhoid fever, and on the differentiation of typhoid and colon bacilli and of pneumococcus and streptococcus, for the staining of the capsules of which he had devised a stain. He also carried on investigations on the nature of immunity, and in collaboration with his assistant, Dr. Hans Zinsser, was the author of a widely used textbook on bacteriology.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE—CONFERENCE ON CLERICAL WORK—CIRCULAR OF BRITISH MEDICAL ASSOCIATION—HOSPITAL SUNDAY FUND—SECTION ON HISTORY OF MEDICINE—ODDITIES OF NOMENCLATURE—STREPTOTHRIX INFECTIONS—OBITUARY.

London, February 14, 1913.

Questions in the House of Commons having extracted the admission that the clerical work imposed on panel doctors was hardly justifiable, the commissioners hastened to invite those serving to a conference for Tuesday last. Nearly 100 attended and were so sympathetically received that they seem to be satisfied that relief will be granted by the issue of less ponderous books of schedules and certificates. Various other questions have been put with a view of showing shortcomings in the Act, but perhaps it would be wiser to neglect the lesser and consider only those which should be included in the promised amendments.

The British Medical Association has sent out a circular to all registered practitioners asking for information and opinions on the Insurance Act and the Regulations. This is in compliance with the recent determination of the special meeting of representatives. Practitioners are asked to say whether they are on the panels and if so willingly or not, if they are, so far, satisfied with the conditions and will renew the contract; or if not satisfied what alterations they desire. If not on the panel would they go on and how many insured persons have come for attendance although entitled to free advice from others. In case government should appoint whole or part time officials to treat the insured who in that area would be likely to accept the post.

At the Mansion House on Monday there was quite a crowded meeting of the Hospital Sunday Fund to consider resolutions brought forward for changing the constitution. The proposer complained that for five or six years there had been discussions and bickerings. He wanted the awards of the distribution committee to be considered at the annual meetings and any objection made to be investigated by an arbitration committee *ad hoc*.

The Hon. Sydney Holland undertook to reply. He said the constitution was drawn up many years ago and the resolutions brought forward would not remedy a single defect that had been alleged, but the council had appointed a sub-committee respecting some details. The Council was elected at the annual meeting and they chose the distribution committee from well known city men who were not partisans of any particular hospital. They tried to exclude any one who had a bee in his bonnet and the committee was about as strong as could be got together. Excess of expenditure in any hospital would be sure to be inquired into as would any complaints as to the grants made. So satisfied was the late Mr. George Herring that he left £600,000 to the fund. Until anti-vivisectionists intervened the decisions had always been received with gratitude by all. The reverend gentleman who brought forward these resolutions was really the mouthpiece of anti-vivisectionists who wanted a grant for a hospital of their own. Discussion was kept up for a couple of hours, after which each of the three resolutions offered was rejected by an overwhelming majority.

The recently formed Section (History of Medicine) of the Royal Society of Medicine has already produced contributions, more or less serious according to the views of the listeners, but none without interest. Sir William Osler, president, took the chair on January 27, when the medical allusions in Bacon's writings were talked of by Drs. G. W. Steeves, Raymond H. P. Crawford, and L. G. Guthrie. Dr. Crawford then showed by lantern slides in the epidiascope some "plague banners" such as were formerly carried in processions during epidemics. Tracing the custom as far back as the end of the sixth century, he made three groups according as the central figure was the Madonna, the Christ, or a plague saint, the last being most commonly St. Sebastian.

Mr. Doran showed by the epidiascope a number of obstetric forceps of the eighteenth century and described the distinctions between them.

Mr. A. G. R. Foulerton thinks streptothrix infections more frequent than is generally supposed. In his Milroy lectures, 1810, he expressed this opinion and referred to 53 cases investigated at the Middlesex Hospital in the previous 10 years. To these he can now add 25, making up a series of 78 in 13 years which he has communicated to the Surgical Section of the Royal Society of Medicine. He is convinced that this report seriously understates the frequency of streptotrichosis in ordinary

hospital practice. It only includes cases in which a streptothrix was obtained by culture on an artificial medium, or typical branching mycelium was identified in stained specimens of material. The list would have been longer if rod-forms or spores had been included, *e.g.* more cases of appendix infection would have appeared. One would hardly suppose that the results at the Middlesex Hospital are exceptional, at any rate as far as hospital practice is concerned, but to determine this question Mr. Foulerton collated this series with cases collected elsewhere in reference to the incidence as to age, sex, occupation, and sites of primary infection. Comparing on these points the 78 Middlesex Hospital cases with Arland's 109 and Rühral's 632, he finds nothing exceptional and suggests that the apparently large number found may have been due to the detection of early cases—especially of mouth and appendix infections. Now early diagnosis and operation should have an effect on the mortality. Among 40 cases of infection about the mouth only one death occurred and that was one of abscess of the parotid region which broke externally infecting the subcutaneous tissue at the side of the neck and thorax, death following from lung complication. Among 20 appendix cases there were six deaths. Of 14 cases of lung infection, nine died, two went to an infirmary in a hopeless condition, one was not traced, one is believed to have been cured and in the other the progress of the disease seemed arrested. The cured case was admitted under Sir A. P. Gould with abscess in the mamma on incising which fecal smelling pus escaped. A streptothrix was obtained in pure culture. Exploring further a sinus was found leading to a small cavity in the lung. No physical signs had been found. Discharge continued for a year but healed at last under large doses of iodide.

The arrested case was admitted with deep-seated ulcer on the tongue and a patch of dulness over upper lobe of left lung. Repeated scraping of the ulcer gave no streptothrix but the sputum yielded abundance, from which a vaccine was prepared and used for many months when the patient seemed quite well and there were no parasites obtainable from the sputum. A small indefinite area of dulness in the lung remained.

Mr. Foulerton dealt lucidly with the method of pathogenic action, differentiating two classes of the parasite and then with the recognized difficulties of accurate diagnosis. Certainty he felt was to be impossible unless definite, branched, mycelial elements, staining by Gram's method, are found, or unless the identity of the parasite is established by culture. This is why cases are overlooked and why he thinks our hospital statistics understate the frequency of the infection.

Mr. Henry Eales, senior surgeon of the Birmingham Eye Hospital and ophthalmic surgeon to several institutions in the Midlands, died on February 8, his sixty-first birthday. He had been vice-president of the Ophthalmological Society and of the Midland Medical Society. He contributed papers on his specialty to the *Ophthalmic Society's Transactions* and other periodicals.

Dr. J. P. Wilton, of Gloucester, where he had practised some sixty years, succeeding his father, who was Mayor of that city during the reform agitation and was also a doctor, died on the 12th inst. at the age of eighty-four. He took his M. R. C. S. in 1852. He held a conspicuous position and was connected with many public bodies in Gloucester and the county. For some time he also took part in the teaching at the Science and Art Department, South Kensington.

Dr. H. W. Hart, of Ealing, has met with his death "by misadventure," as the coroner's jury term it, having taking an overdose of an opiate on account of insomnia which supervened on the death of his wife after an illness causing him great anxiety.

Dr. William Carter, of Liverpool, died on the 2d inst, aged seventy-seven. He had for many years occupied a leading position as a physician and teacher. He graduated in science and law as well as medicine (M. B. Lond., 1864). He became, it seemed naturally, president of the Medican Institute, consulting physician to the Southern Hospital, the Eye and Ear Infirmary, and various other institutions. He was connected with the medical school as a teacher from the early part of his career and filled different chairs, but for the longest time that of materia medica and therapeutics on which he was regarded as a great authority. He was connected thus with the University from its foundation, also with the Tropical School, which he worked hard to promote. Besides these labors he took an active part in many social efforts. He retired only about four or five years ago, the profession as well as Liverpool being the poorer for his loss.

Dr. Alfred B. Duffin, late professor of medicine at King's College and physician to the Hospital, died on Monday, January 10, aged seventy-nine. He had previously held the professorship of pathological anatomy and of clinical medicine. He filled his curriculum at King's and Edinburgh Universities, where he took his M.D. He then went to Berlin and studied under Virchow.

## OUR PARIS LETTER.

(From Our Regular Correspondent.)

THE FIRST INTERNATIONAL CONGRESS OF COMPARATIVE PATHOLOGY—CYSTICERCUS IN DOMESTIC ANIMALS AND HUMAN TAPEWORM—TINEAS IN HUMAN BEINGS—AVIAN AND HUMAN DIPHTHERIA—RABIES AND RODENTS—ANIMAL AND HUMAN TUBERCULOSIS—ROUTE OF ENTRY OF TUBERCLE BACILLUS IN DIFFERENT ANIMALS—RADIOACTIVITY AND VEGETATION—RESOLUTIONS ADOPTED.

PARIS, January 15, 1913.

THE First International Congress of Comparative Pathology began its sessions October 10, 1912, in the large amphitheater of the Medical School, under the honorary presidency of the Minister of Public Instruction. The officiating president of the congress was Professor Roger who in a fine address showed the importance of comparative pathology in the progress of the medical sciences.

In the section on animal parasitology Morot read a paper entitled "Cysticercus in Domestic Animals in Relation to Tapeworm in Human Beings." He discussed the question of prophylaxis and advocated the careful inspection of all carcasses of beef and swine, after their slaughter in the abattoirs. This inspection should include the making of exploratory incisions into the chief sites of election of the cysticerus, which sites are the following: the masseteric, the pterygohyoid, and the cervical regions, the tongue, heart, diaphragm, etc. The speaker asked that a resolution be passed by the congress recommending that the public authorities should es-

tablish a rigid inspection of all foods destined for consumption in order that every possibility of infection might be eliminated. He also recommended that rural populations should be instructed as to the necessity of maintaining cesspools for human excreta, and as to the danger to domestic animals resulting from the deposition of these excreta on fields and pastures. Finally the public should be informed as to the dangers resulting from the use of insufficiently cooked beef or pork.

On the subject of vegetable parasites, M. Bodin presented a paper entitled "Tineas: Human and Animal." There are three kinds of tinea: favus, microsporia, and trichophyton. The clinical manifestations of human infection with any of these forms have been drawn in their larger features. Still points in detail are lacking. Little is known regarding the chemical exchanges and the toxic secretions that are associated with tinea infection. The treatment of these infections is well established. It is easy to cure by means of antiseptics tinea of the smooth surfaces, in which the parasites are superficial. In the case of tinea of the hairy scalp, the matter is not so simple, for until recent years it has been regarded as impossible to disinfect the roots of the hairs, or to mechanically obliterate these roots on account of the brittleness of the hairs. Since 1904 the use of radium according to the method first practised by M. Sabouraud has enabled one to accomplish the above ends. This method has served to form a worthy climax to the scientific work which has made the subject of the tineas one of the finest and most complete chapters in pathology.

"Avian and Human Diphtheria" was the title of a paper read by Professor Arloing. There can be no doubt of the transmission of this disease from birds to human beings. The affections that may be transmitted from men to birds are not always caused by the same microorganism. There may be a reciprocal contagion resulting in a pseudomembranous angina. The diphtheritic affections of fowls in which the Klebs-Loeffler bacillus is not the causative organism may cause a similar affection in human beings. The following preventive measures are recommended: the construction of well isolated dunghills; the prohibition of the use of the water obtained from cisterns that may have been contaminated by animals of the barnyard. It is important that children be not permitted to play with fowl. The curative treatment requires the use of the antidiphtheritic serum. All infected places should be disinfected, the infective foci should be destroyed, and the dead animals should be burned. Measures of prophylaxis in the human being require careful disinfection of the buccal, nasal, and pharyngeal cavities, but principally a careful toilet of the hands before meals.

"Rabies" was the subject of a report by Professor Babès of Bucharest. The canine origin of this disease, as generally recognized, has never been actually proved. It is possible that this disease may have originally developed in certain rodents, such as rats, bats, etc., for rabies is not rare in these small animals. It is thought nowadays that rabies belongs to the group of disorders caused by invisible microbes. Babès would hesitate to admit that the Negri bodies are the specific parasites of rabies. In fact this disease is caused by a filterable virus. The Negri bodies are nevertheless of considerable diagnostic value.

"Tuberculosis in Animals as a Source of Human Infection" was studied by Professor Calmette of Lille. Avian tuberculosis may infect, although rarely, the horse, the pig, the bat, the rat, the monkey, the sheep, and even man. It has been proved that bovine bacilli may play a rôle in the infection of human beings. Although statistics show that human infection with bovine bacilli may occasionally though rarely occur through the medium of milk, it is necessary to adopt sanitary measures to remove the cause of this contamination. Human tuberculosis may be transmitted to cattle.

"The Route of Entry of the Tubercle Bacilli in Different Animals" was the subject of a paper by Professor Vallée of Alfort. This route may be through the lungs, the digestive tract, or the buccopharyngeal region. In man the predominating type of contagion is by inhalation; this is also the type in the case of cattle kept in closed stables. Contagion via the alimentary tract occurs in cattle that are in pasture or that drink at the common pond.

"Radioactivity in Relation to Vegetation" was the subject of a discourse by M. Petit of Alfort. Many investigations have demonstrated the beneficial action of radioactivity upon vegetable life. The addition to an ordinary fertilizer of a double quantity of radioactive manure causes an appreciable increase in the crop and gives rise to interesting fluorescent phenomena. The radioactive manures bid fair to render an important service in agriculture.

The congress adopted the following resolutions: First a resolution in favor of the establishment in all countries of a society of comparative pathology, similar to the one existent in Paris. Second, the dissemination among farmers of a knowledge of the diseases of plants and of the most important measures in preventing or combating them. Another resolution introduced by M. Morot was the following: The inspection of meats should be a careful procedure carried out in all those countries in which it is at present incompletely done. There should be an efficient supervision in all abattoirs by competent individuals.

The next meeting of the Congress will be held in three years. The place has not yet been decided upon.

5. Ophthalmia Neonatorum; Administration Standards. H. C. Greene.
6. Hemangioendothelioma of the Temporal Bone. F. L. Jack. Pathological Report. C. B. Faunce.

3. **Transfusion in Treatment of Ruptured Tubal Gestation.**—R. M. Green believes that direct blood transfusion is a surgical procedure of considerable value in the immediate treatment of ruptured tubal pregnancy associated with excessive hemorrhage, and may to advantage be employed in such cases as soon as possible after the hemorrhage is checked, and under the original anesthesia. Even if the patient's life is not in imminent danger, such transfusion, in serious cases, at least does no harm, minimizes shock and expedites convalescence. In the technique of transfusion, if the Elsberg cannula be employed, it seems advisable not to apply a clamp proximally to the donor's artery unless the compression of the cannula proves

insufficient to control the flow of blood. It seems also advisable not to mobilize the donor's artery completely until the moment when the anastomosis is made, since by this method troublesome hemorrhage from minute arterial radicles may be avoided.

4. **Renal Insufficiency and Mental Symptoms.**—M. L. Neff calls attention to the facts that mental symptoms may be the earliest indications of renal insufficiency; that they are the frequent accompaniments of such a condition; that treatment directed to the underlying nephritis would in many cases ameliorate them; and that a critical analysis of the somatic basis of the psychoses would frequently transfer them from the somewhat mystical realm where they now lie into the domain of general medicine.

5. **Administrative Standards in Ophthalmia Neonatorum.**—H. C. Greene states that the efficient control of ophthalmia in the newborn depends upon the routine use of the prophylactic at lying-in hospitals, and, with few exceptions, in private practice; prompt birth returns; absolute adherence to the reporting law which requires immediate notification of the symptoms of ophthalmia neonatorum; and insistence by the health authorities on constant skilled nursing in all but the lightest cases, the specialist's help at the first suspicion of danger, and if this cannot be had in the parents' home, then prompt transfer of the baby, with mother if possible, to a hospital where expert nursing and special medical care are constantly available.

8. The Colorado Method for the Examination and Care of Public School Children. M. E. Bates.

1. **Pain in Tabes.**—A. McL. Hamilton notes that pains are the most important indication of the commencing sclerosis of the posterior nerve roots, and may be of very early appearance, constituting the only dominant or even apparent symptom for perhaps even ten or twelve years; but the author doubts if there are many cases in which some of the lost reflexes may not at the same time also be detected, especially after a year or two. The severity of the peripheral pains, however, does not equal the socalled abdominal or thoracic crises which are characteristic of tabes and are erroneously attributed to other conditions, often leading to improper medical treatment or surgical interference. The likelihood of error is also increased by the fact that these are of early appearance in one-third of all cases of tabes, and this may be uncomplicated for years. Crural neuralgia of an explosive type is a tabetic symptom, and when it is associated with retraction of the testicle it has led to the delusion that a calculus exists. Two forms of occasional pain may resemble those due to disease of the posterior columns. These occasional pains are the cramplike abdominal pains symptomatic of arteriosclerosis of the big mesenteric artery, and the intermittent claudication due to arteriosclerosis, as well as to tobacco toxemia. In the former the duration of the pain is not so protracted nor is the pain so intense as in true tabes, while the tonic contraction in claudication is the chief feature, and the distress is nearly always confined to the posterior leg muscles. There are anomalous cases, however, when the pains are most extensive in the course of the crural nerve and the muscles it supplies. In all cases of trunk pain of doubtful nature, an effort should be made to investigate a possible history of earlier sensory disturbance, which in true tabes involves the lower extremities. By many clinicians the distinctive character of the fulgurating pains of the lower extremities is considered to be sufficient without the verifying accompaniment of lost pupillary reflexes and absent knee jerks.

2. **Mortality in the Feebleminded.**—L. P. Clark and W. L. Stowell believe that segregation is the ideal remedy for this condition, as it runs counter to no moral, religious, or social law or custom. The practical objections are the enormous expense in providing proper segregation facilities, as the State is now greatly overburdened by taxation in caring for the wards it already has under custodial care, and it is doubtful whether the public can be induced freely to meet the problem in this manner, as it would require ten times the number of institutions we now have. As regards sterilization of the unfit, it is pointed out that a very earnest campaign of education and proof of the harmlessness to the individual is necessary if this plan is to be put in general practice and prove adequate to the size and importance of the problem. At present the laws governing the same in the different States are almost void owing to the general distrust of the whole procedure. Legislation has plainly outrun public sentiment in this direction. The authors believe in the effectiveness of this preventive measure and that it works no harm to any concerned. Another measure is the restriction of the marriage laws so there may be no mating of the unfit. Aside from the fact that the unfit often have little need and infrequently invoke the right of marriage license to propagate, this latter rational but Utopian scheme interests society but little at present. Love in its protean form not only laughs at locksmiths, but gives little heed to social rules and customs running counter to its desires.

3. **Contradictions in the Wassermann Reaction.**—A. L. Wolbarst concludes that: (1) The Wassermann reaction is dependent for its result on the skill and knowledge of the serologist. (2) The results of the test depend in great measure on the perfect standardization of the reagents used; these are subject to variation in the hands of different serologists. (3) As a result of these differences, diversity in results is not infrequent, but insufficient attention has hitherto been given to this particular feature of the reaction. (4) It is a gross error to accept the findings of one serologist as conclusive, particularly if his result is positive and the diagnosis is dependent on his report; his work should be checked up by one or more equally competent workers. (5) If two or more competent serologists report on a given serum, the majority opinion may be accepted as fairly conclusive; frequent reexaminations are always of advantage to the patient. (6) Of thirty-seven cases thus studied for discrepancies, agreement of findings took place in twenty-six cases (70 per cent.); absolute contradiction of findings took place in five cases (14 per cent.); and slight disagreements took place in six cases (16 per cent.). (7) All mention of results of the Wassermann test, in the literature or elsewhere, should be accompanied by the name of the serologist who made the test, in order that the measure of accuracy and skill employed may be estimated. (8) The serologist should be selected with the same care and caution as is exercised in the selection of a consultant or expert in any other branch of medical science.

9. The Serpent's Tooth in Formaldehyde. W. E. Morgan.

3. **Thymic Tracheostenosis and Thymus Death.**—A. Crotti reports two cases of this condition in addition to the five that he has already reported. One of the two patients was an adult, the other a newborn infant; sudden death occurred in both. What may be called a latent thymus hyperplasia may occur in children and not come under the surgeon's care. Sudden death may occur without prior symptoms, but there are generally vague respiratory troubles and other signs of ill health. Certain cases of asphyxia of the newborn are explained only in this way. The most striking symptom of the condition is dyspnea, labored respiration or severe choking spells, often alarming to witness. Tracheotomy is useless with the present style of short tubes and longer ones should be provided with every tracheotomy set. The dyspneic symptoms usually appear early and diminish after the second year of life, rarely appearing later. Pressure on the windpipe by the enlarged thymus occurs either at the superior opening of the thorax (mostly in children) or, especially in adults, between the brachiocephalic trunk and the common carotid. It is usually shown by the autopsy, but in some cases it is not shown, and the author accounts for the latter by the irritation of the inferior laryngeal nerve causing spasm of the glottis. In such cases tracheotomy might be useful. In still other cases direct pressure on the base of the heart, affecting the heart ganglia, may be the cause of sudden death. There are, of course, other causes—stridor and respiratory spasm, such as are caused by adenoids and enlarged glands—and these causes must be considered in the diagnosis. Thymus enlargement frequently accompanies hyperthyroidism and simple goiter, but its relations to the thyroid are not clear.

4. **Boiled and Raw Milk.**—J. Brenneman notes that raw mik and boiled milk are clinically very different foods; that the most striking difference between them as shown experimentally is in their reaction to rennin; that the casein of raw milk, unless modified so that it will not form hard and large coagula offers serious difficulties in digestion that are not present in boiled milk; and lastly that these differences between raw and boiled milk should always be borne in mind in comparing clinical, therapeutic, and experimental results in infant-feeding.

5. **Etiology and Treatment of Acne.**—E. D. Chipman believes that bacteria do not figure in the production of acne unless the sebaceous ducts are occluded. The bacteriological flora of acne is of no importance except in treatment by vaccines, and vaccine treatment is not necessary if one is able to provide for the drainage of the ducts. The logical treatment of acne is local treatment aimed at the proper drainage of the sebaceous ducts, and general treatment that will develop an increased tone in the skin.

8. **Treatment of Trachoma.**—W. H. Harrison states that the surgical treatment of this condition is comprised mainly in expression, which benefits more by the increased and quickened blood and lymph supply it induces than by the small quantity of trachoma material removed. Hot applications after expression are more useful than cold ones and a drop of a 25 per cent. solution of argyrol or some bland oil may be put in the eye and the glued lids should be carefully cleansed every morning. After the acute effects of expression subside, in from five to seven days, and there is no further secretion, inflammation or gluing of the lids, they should be everted and the whole of the conjunctiva of the fornix and palpebral surfaces firmly and rather rapidly rubbed with a smooth pencil of copper sulphate, and this must be repeated daily to secure the best results, care being taken to prevent any traumatism of the corneal epithelium. Assuming that the true principle of the treatment of trachoma is often-repeated acute hyperemia in all the conjunctiva in which there is active trachoma, the copper stick should come in contact daily with all this surface. If thorough expression has been done properly and all secretions are checked before using the copper sulphate, the pain of the application will be gradually lessened and cease but will appear again if, after having been left off, it is begun again. Copper sulphate should not be used when there is a corneal ulcer, an inflammation, iritis, or acute exacerbation, until these have been allayed by proper treatment. Lotions are not indicated and the copper stick should not be used too vigorously or beyond producing the desired therapeutic hyperemia. Ointments and lotions are not, in the author's opinion, as effective as the copper stick.

8. The Action of Scharlach R. Upon *X*-Rayed Skin. J. O. W. Barratt.

1. **Paths of Infection in Genitourinary Tuberculosis.**—K. M. Walker notes that tuberculosis of the testicle, in the great majority of cases, is but a single manifestation of a disease which is affecting the urogenital tract at large. It appears that infection of the testicle takes place in tuberculosis, as in gonorrhea, by means of the cord and not by the blood stream. Cases of hematogenous infection do occur but they are few in number. The evidence in favor of the frequent occurrence of a descending genital tuberculosis may be tabulated as follows: *Clinical evidence:* (1) It is extremely rare to find tubercle of the epididymis without discovering some indication of disease of the prostate or the vesicles. (2) Prostatic tubercle is not infrequently found without any lesion of the testicle. (3) The appearance of a tuberculous epididymitis is often preceded by symptoms of prostatitis or vesiculitis—the socalled prodromi of tuberculous epididymitis. (4) The earliest signs of tuberculous disease are found at the lower pole of the epididymis. This is the first position which opposes the line of march of the invading organisms. (5) Tuberculous disease of the testicle is analogous to acute infections which are known to have been produced by extension from the urethra. The ordinary type of tuberculous epididymitis has no analogy to the hematogenous orchitis of mumps. *Pathological evidence:* (1) Lesions of the testicle without disease of the prostate are rare, whereas tuberculous lesions of the prostate are not infrequently found unaccompanied by disease of the testicle. (2) When tubercle of the testicle is found in association with tubercle of the prostate, the lesions in the prostate generally have the appearance of being older than the lesions in the epididymis. (3) Tuberculous nodules in the lower pole of the epididymis usually appear older than those in the upper pole. They are the first to soften and break down. *Experimental evidence:* (1) Microorganisms and inanimate granules are rapidly absorbed from the urethra and carried to the testicle. (2) A tuberculous epididymitis may be experimentally obtained by inoculating the urethra after having damaged one of the testicles.

2. **Immediate Operation in Appendicitis.**—E. Owen states that appendicitis is different from most other acute diseases in that one cannot tell exactly what is the state of affairs without making an incision. It is generally considered that operations done on about the fifth or sixth day of the disease have a particularly high mortality. The explanation is simple; precious time has been lost. There is apt to be a fool's paradise stage in appendicitis, and it may come early or late in the course of the disease. This

stage is characterized by a disappearance of the pain and a remission in the pulse and temperature. What has happened is that some deeply-seated tension has been relieved and quiet has been restored, at least for a time. The continued rigidity of the abdominal muscles (which probably is still marked) is evidence to the surgeon that the storm-warning must not be lowered, although some heavy clouds have been rolled away and the sky looks brighter. It does not at present seem to be generally realized that the pulse and temperature of a person may be normal in spite of the appendix being gangrenous or perforated; that in some of these stealthy and rapid cases there is absolutely no fullness in the fossa; and that if the chief pathological change in the appendix is gangrene there need be very little local tenderness—for there is no sensation in dead tissue; that as there is no sensation in a mortified appendix, there need be no reflex rigidity of the abdominal muscles covering the fossa; that there being no excitement of pulse or temperature, and little or no local pain or tenderness, the patient may make light of his trouble and that his aspect may be deceivingly cheerful. Thus, in the most dangerous class of cases of appendicitis there may be but little either to cause anxiety or to attract serious attention.

3. **Remote Results of Tonsillotomy and Tonsillectomy.**—H. Whale finds that the disadvantages of tonsillotomy are: (1) The initiation of an infection, whether manifesting itself as tonsillitis, lymphadenitis, or both. Such sequelæ are more likely if a very free and deep removal has been performed than if only a moderate amount of the tonsil has been removed. (2) Recurrence of the trouble for which the operation was performed; except in the case of voice troubles, when recurrence is no more probable than after tonsillectomy. The disadvantages of tonsillectomy are: (1) A risk of serious or even dangerous hemorrhage at operation. (2) A risk of harmful deformity supervening later; the deformities most likely to cause harm are adhesion of the posterior faucial pillar to the posterior pharyngeal wall, and overgrowth of the plica triangularis. (3) A risk of voice troubles supervening later, even without any causative deformity. To any patient who requires operation for some other reason, who has never had any voice trouble, and whose livelihood or occupation depends on the use of the voice, tonsillectomy should be urged with caution. Thus it would appear that tonsillectomy is the more dangerous operation. But with the single exception of voice troubles, it is more likely to permanently cure the complaint for which advice is sought; notably so in the case of tonsillitis or lymphadenitis; moreover these two infections are never initiated by tonsillectomy. It is important to eradicate the lower pole.

5. **Addison's Disease in a Boy Aged Ten Years.**—F. Langmead reports the case of a boy aged 10, who died four hours after admission to the hospital. On the evening before, vomiting had started abruptly, accompanied by restlessness, and followed by loss of consciousness. On admission he was seen to be unconscious, the elbows, wrists, and knees being rigidly flexed, and the fingers extended. The temperature was subnormal and the pulse rapid and weak. The abdomen was retracted. The knee-jerks were present, and the plantar response was flexor. Frequent convulsive seizures occurred until death. The case gave rise to much conjecture as to its nature, and remained undiagnosed until the post-mortem examination. A possible explanation appeared to be meningitis, but the rapidity of its course was against this view. Moreover, the optic discs were normal, and cerebrospinal fluid withdrawn by lumbar puncture showed no abnormality beyond absence of reducing power. The possibility of uremia was excluded by the fact that a catheter specimen of urine was normal. Acetone was not present, an observation which excluded cyclical vomiting from the diagnosis. The pigmentation amounted to no more than a slight diffuse brownness of the skin, including that of the abdomen, and would not give rise to comment in a child of the poor at the end of the summer. Later it was learned by careful questioning of the mother that the pigmentation had been noticed to have gradually deepened for about 12 months, and that the boy had been subject to attacks of diarrhea for several months, and had been slowly getting weaker. The boy's father had died from phthisis ten years before, and two aunts and one uncle of his mother also died from the same disease. At autopsy the body was that of a somewhat wasted boy, the skin showing slight general pigmentation without maculæ. The suprarenal glands were fibrocaseous, almost throughout, merely a narrow margin of healthy gland tissue being discernible, and this only in a few areas. The fibrosis had spread into the adjoining posterior abdominal parietes, and must have involved the sympathetic ganglia, though these were not recognized. Caseous glands were found in the portal fissure and two caseous foci in the lowest lobes of the lungs, near the roots, probably representing glands also. Microscopically the tuberculous nature of the process was apparent.

8. **Action of Scarlet-R upon X-Rayed Skin.**—J. O. W. Barrett has found that in old *x*-rayed skin of the rabbit's ear the injection of a solution of Scarlet-R is followed by epithelial proliferation, which may reach an extreme degree, provided the destructive effect of the *x*-radiation has not been excessive. A marked tendency to sloughing is observed when Scarlet-R is injected into old *x*-rayed tissues, the tendency being greater the more marked the extent to which the appendages of the skin have been destroyed.

8. Three Cases in Midwifery Practice. J. Reid.

1. **Immediate Operation in Appendicitis.**—By E. Owen. (See page 446.)

2. **Function of the Appendix and Origin of Appendicitis.**—E. M. Corner notes that lymphoid tissue is the characteristic feature of the cecal apex. The vermiform appendix of man is represented in the vertebrate kingdom by a mass of lymphoid tissue, situated most frequently at the cecal apex. As the vertebrate scale is ascended, this lymphoid tissue tends to be collected together into a specially differentiated portion of the intestinal canal, the vermiform appendix. The vermiform appendix of man is not, therefore, solely a vestigial structure, though it undoubtedly represents the terminal part of the cecum. On the contrary, it is a specialized part of the alimentary canal, Nature having made use of a disappearing structure and endowed it with a secondary function by giving it lymphoid tissue to protect the body against the micro-organisms in the ileocecal region. One well-known property of lymphoid tissue is that by producing leucocytes it is actively protective to its possessor against foreign invaders. Situated in a blind tube in whose lumen are represented types of the organisms inhabiting the large bowel and their fermentations, the lymphoid follicles must have a great deal of work to do, more even than the tonsils, to which the appendix has been likened. The tonsils undergo fibrosis or chronic inflammation without the occurrence of an acute attack. In a like manner similar changes occur in the appendix, but unfortunately there is a very marked difference. Fibrosis of the appendix interferes with the

efficiency of its peristaltic action and the tube becomes incapable of emptying itself. By these means a vicious circle is established; the more pabulum which remains the more will bacteria flourish, and the more likely is it that the chronic inflammation will progress, and the organ become still more incapable of performing its own evacuation. Such a condition may he aptly called appendicular constipation. The inspissation of the contents will lead to the formation of an appendicular calculus or fecal concretion, which may be likened to scybala elsewhere in the large intestine. The results of chronic appendicitis may be at times far more extensive than this. The fibrosis, with its subsequent contraction, leads to further disappearance of the lymphoid follicles and impairment of the muscular action. The appendix consequently becomes an inert breeding ground for microorganisms, and if they escape into the cecum the multiplication is continued there.

6. **Problems Connected with Rheumatoid Arthritis.**—F. G. Thomson discerns a strong family resemblance between Raynaud's disease, rheumatoid arthritis, and exophthalmic goiter. Whatever its relationship to other diseases, rheumatoid arthritis presents in itself many points of interest and many features of obscurity. On the clinical side a wide field of investigation is afforded in the systematic and careful consideration of family history and individual peculiarities in so far as they indicate a personal factor predisposing to the disease, together with precise investigations as to the nature and significance of the so-called accessory symptoms as they affect the nervous and vascular systems respectively. On the pathological side one requires to know what relationship, if any, exists between the various foci of infection which frequently precede the disease and the subsequent phenomena, and more especially the importance of gastric and intestinal toxemia as an etiological factor. It is possible that expert bacteriological examination of the flora of the gastrointestinal tract in a series of cases might throw considerable light on this aspect of the question.

7. **Acute Pneumonia Occurring During Treatment with Arsenic.**—F. Parkes Weber reports a series of cases of pneumonia occurring among childen and other young persons undergoing arsenical treatment. He believes that the arsenic, while predisposing toward pneumonia, also exerts a favorable effect on the reaction of the body toward the disease—that is to say, that when pneumococcal pneumonia occurs in patients who are being treated with arsenic the pneumococcal infection is quickly and successfully resisted. Perhaps later on some arsenical compound like salvarsan or neosalvarsan will be found to have a beneficial effect in pneumococcal pneumonia or other pneumococcal infections, and it might be worth while to try the effect of arsenical preparations, in regard to experimental pneumococcal pneumonia, in some of the lower animals.

*February* 10, 1913.

**Narcolepsy.**—Klieneberger relates a case of this mysterious affection, and describes the seizures to which the patient was subject under four heads. First, he slowed up suddenly in walking but did not stop; in a few minutes he quickened up to his usual speed. Second, his acts were suddenly arrested midway, the muscles not relaxing. This inhibition would last for a few seconds when the intended movement would be completed. Third, there was arrest as before, whereupon repeated efforts were made to execute the movement with no actual progress. Fourth, there was a much more complicated attack. A movement was arrested, as before; whereupon peculiar movements were made with the fingers, which were spread apart, or used in feeling and handling objects, as in delirious conditions. There was no change of color during the attack. There were no tics save for an occasional grimace and nictitation, but these were also present to a slight extent under ordinary conditions. In general the neurologic examination was negative. The patient, who was aged 20, could not have been an epileptic, as the attacks could not be confounded with *petit mal*. There was absolutely no clouding of consciousness, but simply an inhibition of motion. As to the psychogenous origin this was by no means evident. The patient was absolutely free from hysteria, having neither the stigmata nor the constitution. The condition is perhaps best explained by the theory of a special neurosis. Characteristic was the extreme periodicity, and patient also suffers from periodic headaches, migrainoid with scotomata. The narcoleptic attacks amount to as many as 100 attacks daily.

**Lepra Bacilli in the Blood.**—Rabinowitsch has made a somewhat startling discovery in regard to the bacteriology of leprosy which appears to show that our modern knowledge of the heredity of the disease may require revision. The author studied more especially the blood of miscellaneous lepers and fetuses, making use of Uhlenhuth's antiformin method. The finds in patient's blood were not constant, and it was necessary to make repeated examinations as a rule. Positive results were obtained in six lepers and one fetus. These appear to show that the bacilli may pass from the maternal blood directly into the fetal circulation, and that it is possible for the child to inherit the disease, although as in the case of tuberculosis this mode of transmission may be rare.

**Methyl Alcohol Poisoning and the Action of Toxic Peptides.**—Segàle refers by the term toxipeptides to any sort of meat or other nitrogenous food poison. The latter play more or less of a rôle in cholera, ptomaine poisoning, sausage poisoning (bacillus botulinus) and the like. The general picture of these poisonings resembles somewhat intoxication from methyl alcohol. The author lays stress upon the fact that the latter is less toxic than ethyl alcohol, but is not quickly oxidized into harmless bodies. In like manner other theoretically toxic substances may be rendered comparatively harmless. Another element to be reckoned with is anaphylaxis. A second exhibition of methyl alcohol to an experiment animal may cause a much more severe reaction than the first and this fact of course complicates many cases of peptide poisoning. A strong point of difference between the two types of poisoning is as follows: Methyl alcohol is a highly diffusible substance, while the toxic peptides are the reverse. The author touches on the subject of "spontaneous" intoxication. In the case of a man not known to have taken poison a refractive method used by the author in doubtful cases justified the clinical diagnosis of wood alcohol poisoning. Other biophysical or biochemical tests of the patient's serum refer to osmotic tension, concentration of ions, and electric conductivity. Doubtful cases may also be tested by anaphylaxis.

*February* 11, 1913.

**Painless Confinements.**—Voll describes a method which he is employing with success. He regards the half-sleep as unsuitable for private practice, Jaschke is right in not wishing to eliminate maternal consciousness. The author used to give a large dose of morphine through the action of which the women were not fully conscious of the pains, which as a result seemed to be better. They were also less frequent, something not desired, but still serviceable in the protection of the perineum. When the expulsive period has arrived the author simply injects directly into the perineum a mixture of cocain and adrenalin. He first disinfects the perineum with benzine. The needle is inserted 2 cm. to one side of the raphe and the solution directed toward the latter. Laceration seldom oc-

curs and when it does suture may readily be applied. The placenta follows in about an hour without serious hemorrhage.

**Familial Incidence of Atheromatous Tumors.**—Schneider mentions the increasing number of diseases and anomalies recognized as hereditary. Recently he has had the opportunity of tracing wens through five successive generations of a stock. But little is said of the clinical aspect of the wens—their number, size, location, etc. From the great frequency of these formations it should be difficult to prove that incidence represents heredity, but this he believes he has done because of the peculiar selection shown in family members. The author himself belongs to the stock and this gives him unusual opportunities for observation. The first generation is represented by a woman with atheroma. In the table given all descendants under the age of 12 are omitted. In the second generation are two sons, one of whom had the anomaly. The other, with his posterity, remained free. The male of the second generation had five sons, who remained unblemished, and four daughters, three of whom exhibited wens. This alternation of sex in the descent is significant. Of the three marked women of the third generation one left no descendants, and not one of the five males handed down the anomaly. One of the affected women had a son with wens, but the other upset the alternation of sex in part because her sons escaped, with the exception of a twin whose mate was a female. Two other daughters were also victims. One son, himself free, begot a son, sole representative of the fifth generation, who has the familial ailment. The male of the second generation had a progeny, of which 33 1/3 per cent. were affected and the prolific woman in the third generation had 40 per cent. of her children involved. The only father in the fourth generation shows thus far 20 per cent. involved. With sufficient fertility the family might be mendelized. It is, of course, possible that not all the atheroma cases were inherited.

**The Pocket Flashlight in the Diagnosis of Hydrocele.**—Mayer speaks of the difficulty in diagnosis in hydrocele at its earliest stages when the light available is not sufficient. As nearly every rural practitioner carries one of these lamps in his pocket he can use it for testing the transparency of a tumor which appears to be solid. The incandescent lamp should be placed close behind the scrotum, whereupon if hydrocele is present the shadow of the testicle is seen sharply contoured against the brighter area of the fluid. The ordinary bulb for illumination may also be utilized if the skin which touches it is protected by cloth. The larger the hydrocele the more brilliant the test.

---

## Deutsche medizinische Wochenschrift.

*February 6, 1913.*

**Supersensitiveness to Arsenic.**—Kaufman, commenting upon Straubli's recently reported experience of arsenicism after injections of cacodyl states that he has also witnessed the local but never the general phenomena. The phenomena were quite constant. After from 2 to 4 injections had been sustained without any reaction whatever, every subsequent injection caused the production of a large firm infiltration *in situ* the size of a silver dollar or thereabout. This felt warm and itched violently, was not, in the least painful and underwent involution with desquamation in the course of a few days. The phenomenon suggested in every way not simple irritation but anaphylaxis—chiefly of course because the former was not in evidence at the outset.

**The Normal Body Temperature of the Child.**—Dr. Dora Fraenkel has studied this subject with especial reference to the influence of rest and motion. She introduces the well known fact that healthy children sometimes run a slight temperature. Jacobsen saw subfebrile temperatures last for weeks and months which did not subside until the tonsils were removed. Avellis never saw this sequence and his opinion of some of the subfebrile rectal temperatures was that they were due to local conditions—as the action of heat forming bacteria. Czerny believes in a "visit temperature" in sensitive children and Pfaundler thinks an elevated rectal temperature is normal in some neurolymphatic children. Authors also differ notably in what constitutes normal temperatures. The limits vary from 36.8° to 37.9°. An evening temperature of 37.5° appears to represent the average. The author's own work in the Borgsdorf Hospital for Children (Berlin) gives surprising results, for the supposedly afebrile children nearly all show an evening temperature of from 37.6° to 38.5°. A series of 163 supposedly nervous or scrofulous children chiefly between the ages of 5 and 13 furnished the material which moreover was quite free from enlarged tonsils and adenoids. Deep rectal temperatures alone were taken. With regard to the influence of motion and rest, the former in the form of play and exercise can cause temperatures of over 38° in all children. This as a rule subsides after resting. Neuropathic children are more responsive in this respect than the non-neuropathic. Children with positive von Pirquet behave like intact children in this respect. At best we should not find over 37.2 rectal in the healthy child.

**Significance and Practicability of the Prophlaxis and Treatment of Diphtheria.**—Braun, in the course of a long article makes the following points. In regard to the claim that the prophylactic action is very brief he asserts that at least three weeks immunity is conferred to a certainty, after which in individual cases it may be prolonged, say up to three and four months If new cases develop during this period they are extremely mild. In regard to anaphylaxis, it has become a bugbear with many institutional physicians because it antagonizes the idea of prophylactic injections. They mostly prefer on that account to reserve the first injection until the disease has actually been contracted. The author can only oppose to this argument that he sees no anaphylaxis in his practice as far as a single prophylactic injection is used. Anaphylaxis is to be feared when in the course of a year a number of injections are given at considerable intervals. This necessity cannot often occur. In subjects who have at intervals anginæ which are diphtheretic or diptheroid, a small therapeutic dose will do better than a large immunizing dose. The argument against serotherapy which is most difficult to answer is the great cost of the serum and of its exhibition. Proper prophylactic injections may greatly cut down expenses. The author proved this in connection with his own division of the Friedrichshain Hospital (Berlin). The organization of the official and semi-official medical men with respect to the carrying out of a definite campaign against the disease is, of course, of great assistance.

---

**Diaphragmatic Hernia.**—K. M. Vogel concludes that diaphragmatic hernia is much commoner than is generally supposed, and may exist indefinitely without giving rise to symptoms. Dextrocardia and physical signs suggesting those of pneumothorax should always cause the possibility of this condition to be thought of and lead to careful radiographic study of the thorax.—*American Journal of the Medical Sciences.*

**Rôle of the Lipoids in Narcosis.**—B. Kramer finds that the intravenous injection of five to thirty cubic centimeters of a 5 or 10 per cent. emulsion of lecithin, depending upon the size of the animal used, does not interfere with the induction of anesthesia, and this can be accomplished as readily in animals thus injected as in controls. In six out of nine experiments lecithin had no effect upon the rapidity with which the various phenomena which indicate the animal's recovery from the effects of the anesthetic appeared. These experiments do not bear out Reicher's assumption as to the cause of the lipoidemia, and the explanation of this phenomenon still remains an open question.—*Journal of Experimental Medicine.*

## Insurance Medicine.

**The Upward Trend of Mortality in Middle Life and Old Age.**—At a meeting of the American Association for the Advancement of Science, Section I., at Cleveland, Ohio, January 3, 1913, Mr. E. E. Rittenhouse, conservation commissioner of the Equitable Life Assurance Society of the United States, spoke on the marked increase in the death rate of men of 40 years and over during the past twenty or twenty-five years, and quoted some interesting statistics in proof thereof. He enumerated some of the causes of this increase and how unnecessary it was, and said that every postponable death among policyholders increased the cost of life insurance. The mortality gains—which are the annual amounts by which the expected death claims exceed the actual claims—go into the surplus from which dividends are paid to stock and policyholders. Therefore, if the present mortality rate among policyholders could be materially lowered, the cost of insurance to them would be correspondingly reduced.

The Equitable Life Assurance Society, and three or four other companies have assisted by organized effort and actual expenditure of money, in advancing the campaign to promote longevity; and it is urged on all insurance companies to do the same. In infancy, childhood, and early adult life, where the proportion of policyholders is smaller, the death rate has been decreasing for years; while in middle life and beyond, where the larger proportion is found, the mortality trend appears to have been steadily upward, especially in the cities. The mortality experts of the great life insurance companies, recognizing the advancing ratios in the older periods from degenerative causes, have instituted more severe medical examinations at these ages, and in some instances, advance in premiums. But only two companies are giving especial attention in their conservation work to the excessive life waste in these older groups. Physicians and others who have studied this angle of our mortality tendencies recognize the fact that the important and hardest-worked organs of the body are wearing out and breaking down too soon, and that the upward trend in the general death rate in the later age periods is due to the rising mortality rate from the chronic diseases of these organs. Included in this group are apoplexy, paralysis and diseases of the heart, circulatory system, kidneys, and liver. The estimated deaths in 1910 from these diseases in the United States (based upon the registration area) were 367,700. In sixteen cities, from 1880 to 1910, the increase in death rate in these diseases, except those of the liver, was 94 per cent.; in New Jersey for the same period, 108; and in ten registered States for the past ten years, 19 per cent. The most important of the other diseases of middle life and old age that have increased is cancer. The death rate increase in Massachusetts alone from 1880 to 1910 was 66 per cent., and since 1900 it has increased 31 per cent. External cancer alone has increased in the entire registration area 55 per cent. since 1900. The death rate of the total population age 40 and over has increased, 1910, over 1880: In Massachusetts and New Jersey, in 30 years, 21.2 per cent.; in sixteen cities, in 30 years, 25.3 per cent.; in ten States, in 10 years (1900 to 1910), 3 per cent.

The increase in the proportion of older lives in our population has been very slight and does not account for the increase in the death rate. Mr. Rittenhouse quotes Professor Irving Fisher, of Yale, who in his report on national vitality states: "While the death rate of all age periods under 40 has materially decreased, the later periods of life have suffered progressive increase in mortality rate." The statistics given above are quoted as being the most reliable, and while much progress has been made in recent years in popularizing vital insurance statistics, still much more valuable information should be placed before the public in concise and popular form.

To what extent are the adverse mortality tendencies reflected in our total population? In estimating the probable increase for the entire country, the heavy death rate of the populous cities would be reduced by the lesser rate in the rural sections, thus striking a general balance of mortality rate increase. Mr. Rittenhouse states as his belief that in the past thirty years the mortality rate of our entire population in the group above 40 has increased at least 20 per cent., and that the increase is undoubtedly continuing. It seems that we have failed to adapt ourselves to the sudden increase in the life strain, due to our complex and rapidly changing conditions of life. The increase in American life strain is not due only to the high pressure of modern existence. One element of our population is undoubtedly deteriorating from over-strain, due to excessive physical and mental exertion; but a large group is suffering from the excesses of indolence and physical inactivity. The benefit of exercise from walking has alone been seriously curtailed by the advent of cheap transportation through the cities and towns. The tendency of most modern inventions is to reduce physical exercise and to encourage obesity. Even our farmers ride in sulky plows over the fields in which their fathers followed the furrow on foot. Automobiles have brought many people into the open air, but have added to the nerve strain, encouraged physical inertia, overeating and drinking, all of which promote physical degeneration. These are just as important factors in the increasing American life strain as excessive mental and physical exertion. Increased medical knowledge, especially in the field of prevention, and the adoption of more healthful habits of life by some of our people have prolonged many lives in middle life and old age, as well as in the younger ages. This gain, however, is obscured in the older ages by the increasing premature mortality, which appears to result from the unhealthful habits of a still larger group of our people.

All this is absolutely preventable life waste; for it is stated by physicians that fully 50, and perhaps 60 per cent. of the deaths from degenerative affections could be prevented, or postponed for many years by the adoption of ordinary and well-known personal and community health precautions, which include periodical health examinations to detect the existence of these diseases in their incipiency, when they might respond to medical skill. Such an educational movement would not alone extend the years of life, but a vast amount of suffering, poverty, immorality, crime and financial loss which accompanies this life waste would be prevented. The present and future welfare of our race can be guarded in no better way than by waging vigorous and continuous war against the degenerative diseases, which are prematurely blasting and destroying so many valuable American lives.

# Book Reviews.

HEALTH AND HAPPINESS. A Message to Girls from ELIZA M. MOSHER, M.D., member American Medical Association; Lecturer on Special Anatomy, Physiology and Hygiene for Women, Chautauqua School of Physical Education; Formerly Resident Physician to Massachusetts State Reformatory Prison for Women; Professor of Physiology and Resident Physician, Vassar College; Women's Dean and Professor of Hygiene, University of Michigan; Lecturer on Hygiene, Adelphi College, Brooklyn, etc. Illustrated by HELEN MULHERON. Price $1.00 net. New York and London. Funk & Wagnalls Company, 1912.

THE subjects treated in the present volume are uniquely presented in the form of letters, twelve in all. These letters Dr. Mosher has written during vacation hours, each one being sent from some point of interest as Newburyport; Digby, N. S.; York, Me.; Jaffrey, N. H. The style adopted almost persuades the reader that the letters are personal and individual messages. Particular emphasis is laid on habits of posture, good and bad, and their influence on the body. The sanest and simplest ways of acquiring correct habits of posture are pointed out and are made even more clear and interesting by illustrations. The general scheme of the human body is outlined and the relation of health and happiness to structure and function is defined in no uncertain terms. Foods, the removal of waste, the care of the skin, hair, nails, and teeth, and the uses of clothing are discussed not exhaustively but in a practical and helpful manner. In the last letters the writer follows the description of the structure and function of the nervous system with instruction concerning its care from infancy to maturity. The story of motherhood is told in a way calculated to appeal to girls, for Dr. Mosher believes that physical preparation for motherhood should begin in early girlhood. The message must prove helpful to both girls and their mothers.

THE CARE OF THE BODY. By R. S. WOODWORTH, Professor in Columbia University. Price $1.50 net. New York: The Macmillan Company, 1912.

THIS volume is essentially a book on personal hygiene, although throughout the text appear occasional references to the importance of public hygiene. As the writer points out, "personal hygiene is the direct concern of every man, since he must be his own manager in matters of food and sleep, exercise and recreation, and other daily activities which are influential in determining the difference between good health and mediocre health." And while, on the other hand, public hygiene belongs in the realm of the specialist, nevertheless the ideal citizen must realize its importance in the scheme of living. The book is written chiefly for young men. Some of the important topics of physiology are discussed in a practical way, for intelligent individuals demand reasons before they are willing to exert special pains to keep themselves in good condition. This goal can be reached, according to the writer's belief, without either technical medical knowledge or continuous thought about the preservation of health. Various chapters treat of the science of health, the circulation, breathing, food, digestion, wastes and their removal, the work of the body, the ear, the eye, nerve and brain, work, rest and recreation, indulgences, the cycle of life, and disease. The hygienic crank is shown to be "a very poor model of healthy living," for worry while it lasts transforms man into a sort of monomaniac. The writer believes that "scientific hygiene has nothing in common with worry." The understanding of cause and effect must be the foundation stone of a true science of health. The avoidance of excesses is probably the most useful general rule in the care of health, although even here the personal equation is all-important. A man must learn his own measure. The reader's interest is sustained throughout, for the advice given is sane, useful and well adapted to the needs of every-day life. A good index adds value to the work.

SURGERY OF THE BRAIN AND SPINAL CORD, BASED ON PERSONAL EXPERIENCES. By Prof. FEDOR KRAUSE, M.D., Berlin. English adaptation by MAX THOREK, M.D. (Rush Medical College, University of Chicago). Vols. II and III. With 136 figures in the text, 17 of which are colored, 74 colored figures and 4 half-tone figures on 37 plates. Price, $7 each. New York: Rebman Company, 1912.

THE concluding volumes of this valuable work, the first of which was translated by Dr. Herman A. Haubold, constitute a valuable and important addition to the literature of this branch of surgery, which may be looked upon as one of the great achievements of recent years. Professor Krause must be accepted as among the foremost figures in the development of this subject and his personal association with many of the leaders, not only of German surgical but also neurological endeavor, has aided greatly the value and interest of the work. The basis of the book is a series of cases observed and treated in the Augusta Hospital of Berlin, and the various theoretical questions which might arise in connection with the subject are referred to the original monographs. In other words, the author has endeavored to illustrate important morbid manifestations with characteristic clinical observations, based largely on personal observations and operative procedures. The translator acknowledges that he has had a difficult task and plainly states that he has attempted to reproduce the language of the author as accurately as possible. Whether this is an advantage or not must be left to the reader to decide, although it will probably be admitted that a better English and freedom from idiomatic expressions would have added greatly to the pleasure of reading the book. The second volume of Professor Krause's work presents a complete discussion of the general subject of epilepsy and its treatment by surgical measures. The author does not present any favorable opinion as regards the value of the procedure in general epilepsy, although he admits that improvement may occur. In the Jacksonian variety, in which the indications may be formulated with greater precision than in the general epileptic state, better results will be obtained by operative treatment. He believes that the latter class of cases should invariably be treated by the surgeon from the beginning rather than by the neurologist. A discussion of neoplasms of the brain occupies the remainder of the second volume.

The third volume is taken up by the discussion of intracranial suppurations and injuries, together with a complete description of the surgical diseases of the spinal cord, including meningitis, neoplasms, tuberculosis, and injuries.

A very important feature of the book is the large number of colored illustrations, which are taken from individual cases and display very effectively their various details. These illustrations are based on sketches made during the operation, and are claimed to portray the conditions as objectively presented to the eye of the observer. In each instance only the essential details are given, and the attention is centered entirely on the facts under discussion. Such illustrations present an enormous advantage over original photographic reproductions in which the center of interest is usually obscured by surrounding and unnecessary details.

THE PEOPLE'S MEDICAL GUIDE; Points for the Patient, Notes for the Nurse, Matter for the Medical Adviser, Succor for the Suffering, Precepts for the Public. By JOHN GRIMSHAW, M.D., B.S. (Lond.), D.P.H. (Camb.), M.R.C.S. (Eng.), etc. Price $8 net. New York: The Macmillan Co., 1912.

DR. GRIMSHAW has written a good deal of what may be termed popular medical literature and has done it all well. There is still a certain amount of prejudice among many members of the medical profession against the popularizing of medical subjects. There is, however, too, a considerable audience for this class of writing, and after all if the public requires such matter it is better that it should be provided by a competent person than that untrustworthy misleading and harmful statements regarding diseases and their treatment should be sent forth broadcast. Above all it is necessary if medical subjects are to be supplied for popular consumption that they should be presented in clear and understandable language. Dr. Grimshaw is a past master of this by no means easy art, and in his latest book he has given convincing evidence that in this respect his hand has not in the least lost its cunning. In the preface it is pointed out that the present period is characterized by catholicity and that apart from surgery which is making vast strides, and in addition to drugs which are being hobbled by scientic observation under experimental conditions we have dietetics, physical treatment, psychotherapy, organotherapy, chemotherapy, and vaccine and serum treatment. In this work all these various means of treating are explained lucidly, so that the layman may understand with ease not only treatment but how and why disease and infection are spread. A special feature of the book is that sufficient emphasis is placed upon the prevention of disease and the hygienic methods by which this object can be brought about. The author exposes in a fearless manner "the ways that are dark and the tricks that are vain" of quacks, their methods and medicine, and quoting from the analyses of proprietary and patent medicines made by the British Medical Association shows how most of these highly extolled certain cures are worthless when not harmful and bring to their unscrupulous exploiters huge profits. As a work on popular medicine this one is decidedly the best in the field.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held February 20, 1913.*

VICE-PRESIDENT, DR. GLENTWORTH R. BUTLER IN THE CHAIR.

THE evening was devoted to a symposium on hospital and dispensary facilities for the treatment of venereal diseases.

**The Attitude of the Department of Health in Relation to Venereal Diseases.**—Dr. HERMANN M. BIGGS read this paper. He stated that the action of the Board of Health in regard to the reporting of venereal diseases had been taken with a full realization of the difficulties that the problem presented. They had been influenced to this step by the fact that venereal diseases were infectious, highly communicable, and also preventable. The Board of Health was charged by law with the control and prevention of such diseases and consequently the logic of the situation demanded that action should be taken. The Department of Health concluded that its duty was to attempt to deal with the purely sanitary features of the problem from the public health standpoint, while the social and moral phases were entirely ignored. A number of the hospitals had objected to reporting cases of venereal disease and had appealed to the Mayor. The opposition met had been paralleled when some years ago it was decided to make pulmonary tuberculosis a reportable disease. After reviewing the history of that struggle, it was stated that such criticism and opposition had been fully anticipated and much more was likely to follow. Last year Dr. Homer Swift of the Hospital of the Rockefeller Institute showed that there was not a single clinic or dispensary in New York City in which modern methods for the diagnosis and treatment of syphilis were regularly followed. The department did not desire and never had desired to assume any responsibility or to do any work which was being done properly by any other authorities or agencies. The request of the department for a report of the number of cases of venereal diseases treated by each physician during 1912 had up to the present time resulted in the report of 12,525 cases of syphilis, 23,759 cases of gonorrhea, and 4,166 of chancroid, making a total of 40,450 cases, which only represented the cases reported by private physicians. It was probable that 200,000 was nearer the actual number of cases in the city during the year 1912. The department had established a "diagnosis venereal clinic" in July, 1912, and in January an evening clinic for the accommodation of persons who could not well leave their work during the day. The total attendance at the main clinic was 557 since January 1, while the night clinic had averaged six nightly. The policy of the Department of Health toward these diseases at present comprised the following: 1. The development and extension of the system of registration as at present conducted. 2. The provision of adequate facilities for the early diagnosis and subsequent supervision of all forms of venereal disease. 3. The institution of an extensive campaign of education in relation to sex hygiene and as to the cause, prevalence, danger, results of such infections, and the means for their prevention and treatment. 4. The provision of hospital accommodations for such cases as constituted a menace or which could find no facilities elsewhere for their care.

**Dispensary Facilities for the Treatment of Syphilis.**—Dr. HOMER F. SWIFT presented this paper. He stated that the out-patient departments of most of the hospitals had not kept pace with the advances made along scientific lines, so that the treatment to-day consisted chiefly of what might be designated "old fashioned" treatment along with a smattering of the new. The problem of the out-patient treatment of syphilis was peculiar to this disease. Most of the patients were not incapacitated during the early stages of the disease, nevertheless, many of them would be better in the wards of hospitals for a certain time, and the ambulatory treatment of the disease was only one phase of the problem. Up to the present time the classification of the patients had been left to a ticket clerk at the desk who divided the patients into various classes. This classification of syphilis according to the organ involved was an unwise one. The result of such a classification had been that syphilis was regarded as a lot of different symptoms and not as a disease. As long as this view prevailed the treatment of syphilis would be symptomatic and as soon as the symptoms disappeared the treatment would be discontinued. The patient would disappear from view to return, perhaps, to some different room in the clinic. If this view of syphilis as syphilis and not as one branch of many specialties were accepted the dispensary treatment of the disease would be carried on in a room especially equipped, both in men and apparatus for the treatment of the disease. Just who would be at the head of this room would have to be determined in the individual clinic. As syphilis was a genitourinary disease only in the primary stage in men, and in women, in the majority of cases, was untreated until it reached the secondary stage, it seemed probable that it fell more often into the hands of the dermatologist than to the care of any other one specialist. It might, therefore, be better for the dermatological department to supervise and diagnose the treatment. The fact that the disease involved so many of the special organs made it almost necessary to have the help of the ophthalmologist, the laryngologist, and the otologist. The neurologist and the internist might well be included in this special room. The surgeon frequently had syphilis as a primary cause in many of the conditions falling under his care. With a staff consisting of members of all the specialties, the clinical diagnosis would be well looked after. The development of laboratory diagnosis in the last few years made it imperative that proper laboratory facilities should be at hand for diagnosis. If the disease was ever to be eradicated, the early diagnosis of syphilis would have to be made in the majority of cases. The examination of serum from the initial lesion by the dark field microscope was one of the simplest procedures in clinical microscopy. The necessity and importance of such a diagnosis was little realized by the majority of physicians. How little this important instrument was used was well illustrated by reports from a number of clinics in this city. In eighteen dispensaries where primary syphilis was treated, spirochete examination was used as a routine in only five, in ten occasionally, and in three not at all. In only five was there a dark field microscope. The introduction of salvarsan had made this early diagnosis of much more relative importance because the successful abortive treatment of the disease in the primary stage was now possible. Every dispensary should have attached to it an efficient Wassermann laboratory. The reaction was not only of use as a diagnostic measure, but indicated the condition of a patient at a given time, and was also a useful guide in the control of treatment. The careful study of the relative efficacy of treatment had shown that the best forms of treatment, namely, inunctions of mercury or injections of calomel, in the opinion of such men as Neisser, cured much less than 50 per cent. of their patients. At the present time no dispensary could consider that it had done its duty by the patients who placed themselves under its care without the administration of salvarsan in sufficient quantities. The investigations of the past two years had shown that it was necessary to administer this drug in courses of intravenous injections. Such courses should consist of five or six injections at intervals of from five to seven days. The treatment of secondary syphilis with one or two injections without further treatment could not be too strongly condemned. It had been fairly well established that a course of salvarsan was much more effective if it had been preceded by a course of mercury intramuscularly. The great care necessary for the proper administration of salvarsan rendered a special room almost a requisite. If each department in a dispensary tried to administer the drug there was a great loss of time and efficiency. With the same effort in a given time more than double the number of treatments could be carried out in a special room than in several poorly prepared places. The centralization of treatment would lead to more efficient treatment because the methods would be more uniform and larger groups of patients in relatively the same stage of the disease might be followed. The failures of a certain course would be more evident and the plan could be altered in the light of the facts gathered by careful study. Some uniform plan for the instruction of patients in the nature of their disease should be adopted. They should be educated especially in regard to the necessity of continuing treatment even after a symptomatic cure had been effected. It was poor economy, after having invested fifteen or twenty dollars in the treatment of a patient, to allow him to pass on to a condition where fifty dollars' worth of drugs would not cure him. At the present wholesale price a course of six injections of salvarsan cost fifteen dollars. It would be wise for the medical profession to take some concerted action to reduce this cost. The Government collected thirty or forty per cent. of this cost. Both the Government and the manufacturers should be approached in this matter. With regard to the relative efficiency of salvarsan and neosalvarsan, it had been shown that for the same amount of money about twice the therapeutic effect could be obtained from salvarsan as from neosalvarsan. The centralization of the treatment of syphilis would lead to more efficient social

service work. Similar methods might be employed in this line as were used in other branches of the dispensary. The financial condition of the patient should be investigated and those who were able to pay should be compelled to pay for their treatments, while those unable to pay should receive free treatment. The patients who failed to return could be followed up and encouraged to continue treatment until a cure was effected. In the general organization of all the clinics the division of the city into various districts should be most seriously considered. Patients should not be treated in a dispensary outside their own district. An exception might be made in the case of university clinics where as large a material as possible was desirable for teaching purposes. This districting of the city would soon allow a fair estimate of the amount of syphilis in a given district and suitable provision for physicians and equipment could then be made in each dispensary. After all this work was organized, the question of treatment would be only partially solved unless the wards of all the hospitals were opened to patients in all stages of syphilis. Severe early cases and many cases with nervous and visceral involvement should be under ward treatment for a certain period. The work between the ward and outpatient department should be closely correlated.

**Adequate Dispensary Facilities for the Treatment of Gonorrhea.**—Dr. EDWARD L. KEYES, Jr., said that the practical problem of providing adequate dispensary facilities for the treatment of persons suffering from gonorrhea in large cities presented as its chief economic difficulty the time when such clinics should be held. Women patients might be treated at any time during the day, but the wage earner found it extremely difficult to visit the clinic during working hours and, therefore, the clinic for men to be truly efficient should be held in the evening. A second problem was that although the number of clinics for the treatment of venereal diseases in the city was inadequate, nevertheless, it was felt that multiplication of purely venereal clinics unattached to general dispensaries might repel patients who felt the odium of attending such a clinic. This problem, however, was largely theoretical, for a few years ago, and perhaps now, the largest clinic in town was devoted exclusively to venereal diseases and was held in the evening at the Hudson Street Hospital. The clinic for gonorrhea should be diveded into two entirely distinct parts, one for the male sex and the other for the female sex. Gonorrheal rheumatism and conjunctivitis required hospital care. Inasmuch as gonorrhea formed so large a part of clinical work in gynecology it would obviously be impossible to separate the two subjects and, therefore, the clinic must combine the treatment of all gynecological patients with those afflicted with gonorrhea. Special provision should be made for separate sets of instruments for the treatment of gonorrheal and non-gonorrheal cases. The uncertainty of diagnosis forbade precise segregation, yet the mere fact of placing gonorrheal cases in one room to be treated by one set of instruments, and the non-infectious cases in another room would serve as a constant reminder to the members of the staff of the ever-present danger of infection. A small clinic with one or two assistants presented no difficulty for the supervision of patients as this might be made by the chief physician in attendance. It was usually convenient to divide the physicians into two groups, each visiting on alternate days. Some clinics did efficient work although seeing their patients but twice a week. If a larger attendance of patients than ten or fifteen was expcted or desired, certain special provisions should be made for the sake of efficiency. The gynecological clinic required at least one trained nurse for every two physicians in attendance. The clinic should be composed of at least three rooms, viz., waiting room, treatment room, and operating or cystoscopic room. If possible there should be a separate sterilizing room or alcove, and a laboratory for microscopical and chemical analyses. The treatment room should be divided into a number of curtained alcoves, each containing an examining table, a chair, and an instrument table. There should be at least one alcove for each physician in attendance. The precise instrumental equipment of the clinic depended upon the taste and experience of the physician in charge as well as the generosity of the institution supporting the clinic. The social and hygienic side of the venereal problem must be constantly borne in mind. Certain precautions should be impressed upon each individual patient, and the best way was to distribute leaflets emphasizing the chief precautions to all patients at their first visit. They should be printed in different languages. The following was a good sample. It was compiled by the late Dr. Follen Cabot: "Gonorrhea, or 'clap,' is a local contagious disease which requires treatment until the physician pronounces you cured. To avoid infecting others and to prevent complications, as bubo, stricture, swollen testicles, etc., the following rules should be observed: (1) During the first few weeks walking should be limited. When the discharge is profuse you should keep off your feet as much as possible. (2) Do not use alcohol in any form, as it always prolongs the disease. Drink milk, tea, and from six to eight glasses of water during the day. (3) Avoid all sexual relations until you have been pronounced cured by your physician, as the disease may be given to a woman even after the discharge has apparently ceased. When it is present you should avoid sexual excitement, as erections always aggravate the disease. (4) Always wash the hands after washing the parts. The discharge, if carried to the eyes, will cause blindness. (5) Sleep alone, and be sure that no one uses any of your toilet articles, particularly towels and wash cloths. (6) Never lend your syringe to any one, and as soon as you are well destroy it. (7) Be sure that the bowels move every day. If they are inclined to be constipated take a dose of Rochelle salts before breakfast. (8) Do not use ginger ale, mustard, pepper, horseradish, or stimulating sauces on your food."

**Hospital Accommodations for Acute Venereal Cases.**—Dr. S. S. GOLDWATER said that practically there were no hospital accommodations in the city of New York for patients suffering from venereal diseases. Five years ago investigations showed that there were only about 150 beds for male cases and less than 50 beds for female cases, and he believed that that report was fairly accurate. At that time there were but five hospitals in the city of New York that had limited accommodations for patients who were the victims of venereal diseases. The number had since increased. Substantially, however, there was no place for the care of those suffering from venereal diseases in the city of New York. Why? In the first place it seemed to him that there existed among hospital physicians and hospital directors, no well-thought-out theory of hospital organization as a whole. The questions were rarely asked, "What constitutes a hospital? How is the clinical organization of a hospital best made up? What clinical groups of cases, what clinical departments should be recognized in order to insure the greatest efficiency in the treatment of disease, in order to provide for appropriate cooperative effort in complicated cases?" Nowadays cases required the care of a group of men. If they began with that idea in mind they would soon provide in every general hospital in the city some department for the treatment of syphilis and gonorrhea. In the second place many failed to recognize the economic consequences that would follow the failure to treat these cases. Many of these institutions did not know what they were doing when they turned away patients with venereal diseases in the early stages. How would this action affect the hospital later, bringing upon it the necessity of caring for cases in the later and more expensive stages of the disease? There was too much prejudice and a failure to understand certain social facts. Too much emphasis had been placed upon the danger to the hospital workers themselves in the treatment of those afflicted with venereal diseases; danger of infection in hospitals was comparatively slight and least of all in the hospital wards that were specifically set aside for the treatment of these diseases, the nature of which was known. Dr. Goldwater thought there was a misunderstanding in regard to the supposed efficiency of the dispensary treatment of these cases as now practised. If they realized the results that were being obtained their consciences would forbid them to refer these patients to the dispensaries. He said he was glad to hear Dr. Biggs outline the proposed limitation of function of the hospital to be erected by the Health Department for the treatment of venereal diseases. If the department undertook the treatment of syphilis generally it would necessitate a great drain upon the city. He believed that the tendency to establish special hospitals was a danger to the community. He advised the establishment of special departments in general hospitals rather than the further development of special hospitals. In the general hospital, consultants representing all branches of medicine were present daily. One great danger was that the policy of the Department of Health would be pushed too rapidly. It was fair to say that the hospitals had hitherto neglected this work, but public sentiment had been aroused, and the educational movement so far conducted had caused a change of front on the part of hospitals and the public. There was beginning a tremendous movement in the development of hospital work for venereal diseases in the city of New York and the private hospitals would show what they could and would do in the next year or two in the care of those suf-

fering from venereal diseases. Another point Dr. Goldwater wished to bring up was that notification, if insisted upon by the Board of Health, would interfere with the treatment of patients with venereal diseases in institutions. Dreading publicity, patients would turn to irregular practitioners and quacks. It should be the policy of the Board of Health to do what it could toward encouraging the poorer classes to seek treatment in general hospitals and not have them branded as infamous and thus encourage them to turn to quacks. He hoped that the Board of Health would stand aside and let the Academy of Medicine and the associated clinics study the question and see what could be done in the hospitals and dispensaries in the care of patients with venereal diseases. Hypocrisy played a part in the policies of certain institutions, as illustrated to him recently when he made a visit to a neighboring city. He fell in with some trustees of a leading institution where they had a very extensive hospital plant. The hospital had acquired some neighboring property on which were a number of tumble-down shanties. Dr. Goldwater suggested that they clear them away immediately and not wait until funds became available for any further extension of the hospital plant. One of the trustees laughed and Dr. Goldwater asked why he laughed. The answer was that these shanties, which were houses of prostitution, were such excellent rent-payers that they could not afford to give them up. Yet in the hospital which was willing to accept revenue from this source, no case of syphilis or gonorrhea was treated because moral contamination was feared.

**Relation of Syphilis to Internal Medicine.**—Dr. Warfield T. Longcope read this paper. He said that the great importance of syphilis as an etiological factor in many of the chronic diseases that incapacitated the population in the prime or a little after the prime of life was rapidly becoming evident. Principally by means of the Wassermann reaction the dependence of these chronic diseases upon syphilis were becoming clear. The two situations in which the *Spirochæta pallida* seemed most often to persist and where they caused the most trouble were the cardiovascular system and the nervous system. Of the cardiovascular diseases dependent upon syphilis, syphilitic aortitis stood out most prominently. This manifestation usually produced symptoms some ten or twenty years after the primary infection and formed the basis of three very serious conditions, namely, aneurysm, aortic insufficiency, and angina pectoris. It could now be shown definitely that syphilitic aortitis was the direct cause of from 90 to 95 per cent. of all aneurysms of the aorta, so that for practical purposes aneurysm of the aorta meant syphilis. The same disease was responsible for about 75 per cent. of the cases of aortic insufficiency, and anywhere from 30 to 50 per cent. of the cases of angina pectoris in young adults. To syphilitic aortitis must be ascribed a certain proportion of cases of myocarditis and it had been estimated that, excluding aneurysm and aortic insufficiency, about 24 per cent. of patients suffering from cardiovascular diseases gave a positive Wassermann reaction. With generalized arteriosclerosis in only about 12 per cent. was a Wassermann reaction obtained. Of the general diseases next in importance were the bone and joint manifestations of syphilis. It could now be shown that many of the cases of chronic arthritis, osteitis, and periostitis were directly due to syphilis. A certain proportion of the cases of cirrhosis of the liver, too, were caused by *Spirochæta pallida*. Along with cirrhosis of the liver the fact might be mentioned that positive Wassermann reactions have been obtained in cases of splenic anemia or Banti's disease and in some instances these conditions seemed to be dependent upon congenital syphilis. Dr. Longcope said that recently the importance of syphilis as the basis of certain cases of neurasthenia had been forced upon him. Such conditions as paroxysmal hemoglobinuria were accompanied constantly by a positive Wassermann reaction. There were an appalling number of cases of disease of the eye due to syphilis. According to Leber, excluding suppurative cases, the Wassermann reaction was positive in 26 per cent. of cases of retinitis, 38 per cent. of iritis, and 84 per cent. of keratitis. The question might be asked what this meant to the general hospital and to the general public. It meant that in the Presbyterian Hospital as many as one-quarter of the patients in the medical wards were suffering from these chronic syphilitic affections. This meant that it cost the hospital, at perhaps a low estimate, $25,000 a year to care for these individuals. The conditions in diseases of the nervous system were even worse. Practically all cases of paresis were due to syphilis and the brains of these cases might contain at death enormous numbers of *Spirochæta pallida*. Tabes dorsalis must for all practical purposes be considered a syphilitic disease. From the statistics of the State hospitals it was found that 13.3 per cent. of all cases admitted to the State institutions were cases of general paresis, and the total number of patients treated in the State hospitals in September, 1912, was 32,624. If 13 per cent. of these were paretic, it was evident that at this date there were about 4,000 cases of paresis in these hospitals. The care of these patients cost the State nearly one million dollars a year. In Philadelphia, at the City Hospital alone, the cases of paresis, tabes, and cerebrospinal syphilis admitted to the nervous wards formed 15 per cent. of the admissions. Thus one could see what a tremendous economic problem this matter became to say nothing of the humanitarian aspect, and it might safely be said that the two most important and widespread diseases with which they had to deal were tuberculosis and syphilis One hesitated which to mention first. Cooperation of physicians, hospitals, public health departments, and the public seemed almost the only criterion to reduce the incidence and ravages of this ubiquitous disease.

Dr. William S. Gottheil said that he had been much interested in the remarks made by an official of the Board of Health, by a worker in a scientific institution, and by a superintendent of a large hospital; but that he thought it was about time that the medical practitioner should be heard from, who might have something to say slightly different from the views expressed. He did not propose to take up the consideration of ideals of the future, but would speak of conditions as they actually confronted the profession to-day. A short time ago the Department of Health had undertaken to take under its wing the cases of venereal disease in the city, just as they had already done with tuberculosis, throat diseases, eye affections, and many other classes of sick people. An order was issued to the superintendents of all the hospitals to notify the Board of Health of all cases of venereal disease coming under their care, together with the diseases dependent upon them; and such report was to contain not only the names and addresses of the sufferers, but also the names and addresses of the probable source of contagion. With this was coupled a request to the profession at large to do the same with private patients, omitting, however, the names and addresses. This has led to a serious and energetic protest on the part of several medical bodies, both societies and hospital medical boards, who considered the step ill-advised, mischievous, and of use only to the beaurocracy that apparently sought general control of medical practice by giving them apparent facts on which to base demands for more hospitals. With the remarks of Dr. Goldwater the speaker was thoroughly in accord; the public hospitals and dispensaries had not in the past done their full duty to this class of cases, but they were awakening to the fact, and were rapidly endeavoring to remedy matters. Especially did he appreciate the cogency of Dr. Goldwater's remark that it was an unfortunate thing that a rational movement towards improvement in the venereal situation had been complicated and possibly impeded by the attempt at compulsory notification made by the Board of Health. Not only the profession at large but the general public also would object very seriously to any such measure. It was a fact that as compared with many Europeon cities the number of beds specially devoted to venereal diseases was small; but there were many more than the reader of one of the papers stated. There were 150 in one hospital alone with which the speaker was connected and many of these were empty a large part of the time. It must not be forgotten that more than 90 per cent. of all venereal cases were ambulant ones and not hospital cases at all. If more accommodations were needed the remedy was to enlarge the facilities for handling these cases in the municipal hospitals in the various boroughs. The speaker was very grateful to the gentlemen from the Board of Health and the Rockefeller Institute who had instructed him as to the methods of diagnosis and treatment in venereal diseases; and he felt sure that the various learned societies devoted to these subjects and the many able practitioners that composed them would share his feelings. Personally, however, he pitied the would-be syphilographer who could not in forty-nine cases out of fifty make the diagnosis of initial lesion without the dark-field microscope, or that of constitutional syphilis without the Wassermann test. He and all other practitioners in this branch used both measures of diagnosis freely in doubtful cases; but the laboratory results of both tests were distinctly of secondary value as compared with the clinical signs. Finally, the speaker warned the Board of Health that a regulation of the kind they were attempting to introduce was bound to be a dead letter regulation even if they succeeded.

Dr. Henry W. Berg said that to be the subject of gonorrhea or syphilis was believed to be a disgrace and this

was a very important sociological factor in connection with the order to report these venereal diseases and this was without doubt the reason why these victims objected to such reporting. Every patient objected to being disgraced for life, or even for a day. When one reported a case by number, whether of gonorrhea or syphilis, it really meant a report by name and in subsequent years might become an injustice to the patient. A patient with a chancre or with gonorrhea went to the doctor with horror; the younger the patient the greater the horror. A married man might come with an attack of gonorrhea acquired from outside his home, and he asked them to imagine his horror if his case was reported, especially if he resided in a small village. Suspicion might even fall upon his wife. They had no right to tell the innermost secrets of any man's life and this he believed was the essence of the question then before them. What they should strive to do was to clean up the people who gave gonorrhea and chancre. Dr. Berg said he did not feel that he had any right to report cases of venereal disease until the Supreme Court had passed upon it; after thirty years of activities in the medical profession he said he did not feel safe in taking the risk of a damage suit because he reported a case of gonorrhea or syphilis which might have disgraced some woman. He would not do this because he was more or less selfish. This was not a scientific matter but a sociological matter and he differed with Dr. Biggs regarding the desirability of reporting these cases. As to the request to report cases of gonorrhea or syphilis among the poor that went to the hospitals, he feared that these poor people would not want to be reported. Dr. Berg advised those present not to sign any card, but let the patient sign it. To report a dispensary patient by name and a private patient by number was an invidious distinction. He asked that those present should negative any reporting of syphilis or gonorrhea in the city of New York if any resolution to this effect was brought up before them.

Dr. Hermann M. Biggs said that the Department of Health respected all that had been said by the speakers, but what he had brought before them had been under consideration for three years before it had been determined upon. He did not quite understand why those afflicted with syphilis or gonorrhea should so keenly feel the disgrace, nor how the doctors could reconcile their attitude regarding these reports, when they knew they could go into any hospital and find complete records of those who had syphilis or gonorrhea and diseases dependent upon them. These reports were open to anybody who desired to see them. Nobody was prosecuted for placing the facts in the records. These records were placed on the heads of the beds. The Department of Health records were absolutely board records, and divulging their contents would be considered a misdemeanor. What they demanded of the dispensaries were complete and accurate histories, and they promised and assured them that these records would be kept confidential.

Dr. Homer F. Swift said he wished to correct any impression that he might have made that he was too dogmatic as to how syphilis should and should not be treated. He called attention to the facilities they had during the last few years and he tried to bring out the fact that they had good men working on the subject. He thought that some of the remarks made favored increased facilities in the treatment of this disease. Many of the things brought forth were well established. If he seemed to have been too dogmatic in his statements he said he wished to apologize.

**Resolution Regarding the Treatment of Venereal Diseases.**—The following resolution was read and then referred to the Council of the Academy for action and recommendation:

"Resolved, that the New York Academy of Medicine (1) is opposed to the establishment of a clinic for the treatment of venereal diseases by the Department of Health until it has proved that the existing dispensaries, private and public, cannot be made adequate to the needs of the city. (2) Approves the facilities for the diagnosis of venereal diseases which the Department of Health affords through its laboratories. (3) Is in favor of reporting hospital and dispensary cases of gonorrhea and syphilis to the Department of Health under the regulations promulgated by that department and of the uniform use of such nomenclature as may be approved by the Department of Health. (4) Favors the establishment by the Health Department of hospitals for the care of those in certain stages of venereal infections. (5) Favors action leading to the admission under suitable precautions of acute stages of syphilitic infection in the wards of general hospitals. (6) Favors the establishment of a special department for the treatment of syphilis in every general dispensary desiring to treat these diseases. (7) Recommends the formation of an Association of Gastrourinary and Syphilitic Departments of general dispensaries in this city, possibly in connection with the Associated Out-Patient Clinics of the City of New York, for the purpose of coordinating and standardizing the medical and administrative work in connection with venereal diseases. (8) Favors measures, such as the abolition of duties, which may reduce the cost of salvarsan. (9) Is of the opinion that it would be helpful in attacking the problem of social diseases if newspapers in discussing these diseases used the names syphilis and gonorrhea."

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Adjourned Meeting, Held January 31, 1913.*

The President, Dr. Charles Gilmore Kerley, in the Chair.

**Address of the Retiring President.**—Dr. Charles Gilmore Kerley made a brief address in which he thanked the members for the support they had given him in his work during his term of office.

**Inaugural Address of the President-Elect.**—Dr. Brooks H. Wells, after making a grateful acknowledgment of the honor conferred upon him and expressing his appreciation of the responsibilities of his office, said that neither the honor nor the responsibilities were to be minimized, for this society was the representative of the medical profession of the greatest city of the western world and had traditions to remember and duties to perform which were of vital interest to the profession and to the State. Dr. Wells reviewed the history of the society since the time of its incorporation in 1806 in respect to the regulation of the practice of medicine and surgery in this State. From 338 members in 1806 the society had grown in 1912 to 2,469. There were some 2,000 eligible physicians in the county who did not appreciate the duty, the value and the privilege of membership. The duty of the membership lay largely in the fact that the power of the Society both in uplifting and in protecting the material interests of the profession must be in direct proportion to the number, the personal endeavor, and the loyalty of each one, and in the fact that the State in granting privileges imposed obligations which they should not shirk. The direct value and benefit of membership included, besides the value of a better standing in the profession and in the community, the Medical Directory, the State Journal of Medicine, defence against malpractice suits, indorsement upon removal to other States or counties, membership in the State Society, eligibility to the American Medical Association, and participation in the scientific work of the Society and the social hour after the meetings. Each member should influence and bring into the ranks some one of the two thousand who was now neglecting this civic and professional obligation. One of the reproaches of the medical profession was that in general it was indifferent to the welfare of its fellow practitioners. If this were even partly true it was another reason for membership, for one of the objects of the Society was the betterment of the economics of medicine. No other organization could do so much in New York City to advance professional interests as the County Society. In this respect it differed from private societies whose sole object was the promotion of science and good fellowship. It was for the members of this Society to maintain and to strenuously fight for the honor, the high ideals, and the personal integrity of all the members of the profession and especially for these qualities in the members of the County Society. In so far as they failed in this they lost respect both in their own eyes and in the eyes of the public. One had not done his duty when he had merely joined the Society but he must feel that he was personally responsible for the good name and efficiency of the organization. Thus far he had considered the matters that came within the executive functions of the Society but they should not forget the importance of the scientific work. This was equally essential for the existence of the Society. Here there was much for each of them to do and each should have the confidence to present his own best work, yet he should have something of new interest to say to his audience and should say it briefly. Though it seemed that much had been said on every subject there were still many fields that lay fallow, as, for instance, that of cancer. One of the important matters worthy of the attention of this Society was the acquirement and dissemination of knowledge among the people of the necessity of the early recognition of the

signs leading toward the early diagnosis of cancer of the uterus. The signs of this disease, the means for reaching an earlier diagnosis, and the dangers of delay were known, so that there was no excuse for letting women go until the time for successful intervention had passed. Much could be done if each member of this Society would make it his duty to spread among his women patients knowledge of the early symptoms of cancer and of the possibility of its cure in the very early stages. The known fields of medicine, however apparently well mapped out, had many spots where the patient explorer would yet uncover unexpected values. From the pinnacles of present achievement they looked over the future and through the rifts in the clouds of the unknown caught glimpses of fertile valleys and giant peaks that inspired with the invincible determination to win in their untrodden heights.

**The Practical Value of the Negri Bodies from a Diagnostic Standpoint.**—Dr. S. R. Klein read this paper. He stated that with the exception of the Negri bodies no characteristic anatomical or histological changes were found at necropsy in sections of the brain, meninges, and spinal cord from cases of rabies. With regard to the virus nothing definite was known. Experimentation had shown that the poison was connected principally with the nervous system, especially the spinal cord. It destroyed the nerve cells. The virus of rabies was of two kinds, the "street virus" and fixed virus. The virulence of the "street virus" was variable and when inoculated subdurally into rabbits it produced the symptoms of rabies at a variable period of more than fourteen days as a rule; the fixed virus was modified from the street virus by passage through a long series of rabbits. In this way the virulence was increased for these animals, so that they finally took the disease after a certain fixed period of incubation. This form of virus, after attenuation by desiccation, was used in the Pasteur treatment. Negri found within the nerve cells of various portions of the central nervous system of animals which had died of rabies sharply defined round or oval microorganisms from one to twenty-five, but averaging four micromillimeters in diameter; these he considered to be sporozoa. They consisted of a mass of protoplasm containing inner bodies, segment; and spores, and were of constant occurrence in all stages of hydrophobia. These bodies were found in all animals, whether they had died of the natural or artificially induced infection. They were not demonstrable in normal animals or in such as had died of other infections. In subdural infection they were found most frequently in Ammon's horn; they were not observed, however, in all portions of the nervous system, a fact which led Negri to assume that the parasites probably occurred in another form in these localities. The staining process used by Giemsa stained the cytoplasm of the bodies blue and the central bodies and chromatoid granules blue, red, or azure. Generally the larger bodies were a darker blue than the smaller; the smallest might be very light blue. For diagnostic work the smears should be made from at least three different parts of the gray matter of the central nervous system, from the cortex in the region of the fissure of Rolando or in the convolution around the crucial sulcus, from Ammon's horn, and from the cerebellum. In many animals smears were made from the cerebral cortex around the fissures of Rolando and Sylvius, from the olfactory bulb, Ammon's horn, the cerebellum, the medulla in the region of the roots of the cranial nerves, the spinal cord in the dorsal and lumbar regions, the salivary glands, the suprarenals, and some of the peripheral nerves. The following was a short and well recommended method of staining for diagnostic purposes: Place the smears in methyl alcohol for five minutes and then in equal parts of Giemsa solution and distilled water for ten minutes. In this way the bodies were generally brought out well enough for diagnostic purposes, and sometimes the solution showed the structure distinctly. Negri bodies were found before the beginning of symptoms, usually on the fourth day, when fixed virus was used, and on the seventh day, when the street virus was employed. Negri bodies belonged to the class protozoa because they had a definite morphology which was constantly cyclic, that was certain forms always predominated in certain stages of the disease. Negri bodies also belonged to the microsporidia. They were living organisms and the cause of hydrophobia. When they were found rabies could be safely diagnosed. If not found and the specimen was fit for inoculation into a rabbit the biological test could be applied, and in a few cases it succeeded where the Negri bodies had been missed by the microscope. It was evident that early diagnosis was important. While the Negri bodies were easily found in the brains of animals dead from street virus, they were with difficulty found in fixed virus brains and then only in a very minute form. All observers agreed that rabic virus filtered through a Berkfeld candle retained its virulence. The larger Negri bodies could not pass through this filter, so if, as Negri held, the brain was thickly studded with minute forms of spores which were unstainable or ultramicroscopical, and therefore invisible, the filtrability of the virus was an argument in favor of the parasitic nature of these bodies. The Negri bodies might be described as oval, round, or triangular in shape, according to their position in the cell. They were strongly eosinophilic and consisted of a fundamental homogeneous substance, non-granular and hyaline in appearance, resembling coagulated albumin. Within them were clear shining areas, which at first sight appeared to be vacuoles, but under higher powers showed points of deeper color. They were quite resistant to external agencies. Material might be preserved in glycerin for eighty days without altering the Negri bodies. They were destroyed by a thirty-three per cent. solution of caustic potash. They were especially numerous in cases of rabies of long incubation period. Babes believed them to be encapsulated parasites undergoing involution or degeneration. After referring to the staining methods of different investigators, Dr. Klein described Pasteur's method of immunization, which was as follows: Rabbits were inoculated subdurally with the fixed virus daily. At death the spinal cord was removed with strict aseptic precautions, cut into three pieces and suspended in large bottles having an opening near the bottom as well as at the top and which contained a layer of caustic potash. Both openings in the bottle were plugged with cotton to permit of a free circulation of air. They were kept in a dark room at a constant temperature of 23 C.; thus a full series of cords from fourteen days to one day old was at hand, giving the various attenuations of the virus from the weakest to the strongest. The usual dose was a portion of cord from two to three m.m. in length, which was prepared for injection by filtration and suspension in normal salt solution or bouillon. After many experiments on dogs it was determined to try the virus on man. Dr. Klein then related the history of Joseph Meister, the first patient upon whom the treatment was tried. In Hungary from 1890 to 1895, 5,899 persons were bitten by dogs; of these 4,914 received the Pasteur treatment and the mortality was 1.20 per cent., while among those who were not treated by this method the mortality was 14.94 per cent.

**The Water Trap Stomach.**—Dr. G. Reese-Satterlee and Dr. Leon Theodore LeWald presented this communication. They were of the opinion that the water trap stomach was a distinct condition which sometimes might become very serious. The etiology was somewhat uncertain, but one factor was embryological development. A long gastric omentum would predispose to a sagging along the lesser curvature, while the pyloric end remained fixed by its attachment to the spine and the ligament to the liver. The natural result from indiscretions in diet and exercise too soon after heavy meals and with a loaded colon would be to drag down the more dependent portion of the stomach. As a result the organ took the shape of a drain trap and the lower part contained the partially digested food which caused a number of symptoms called indefinitely indigestion or gastritis. A constant drag of the elongated stomach and ptosed colon affected the visceral nerves and resulted in neurasthenia. Tight lacing was also a probable factor, as nearly all cases occurred in women. Possibly the so-called habitus enteropticus and the narrow costal angle and wide pelvis might have an influence, although this predisposed to a more general visceroptosis, which had not usually been present in the series of cases under consideration. Gastric analyses showed nothing very characteristic, though generally there was a low hydrochloric acid content and no excessive amounts. The markedly residual stomachs showed the remnants of previous meals. The stools usually had particles of undigested food, especially meat fibers. In studying the radiographs, the length of the stomach varied from nine to fifteen inches, averaging 10½ inches, all being abnormally long organs. The distance from the upper part of the curvature of the duodenum to the most dependent portion of the greater curvature, called the pyloric arm, varied from 5¼ to 9½ inches. In other types of stomach, this distance was usually 1½ to 3 inches. The average length of the pyloric arm in the sixteen cases reported was 6½ inches. The distance of the most dependent portion of the greater curvature below the umbilicus, or a line drawn across the upper level of the pelvic bones, varied from 3 to 8 inches. This distance in normal stomachs averaged 1½ inches. These measurements were all taken a few minutes after the administration of a bismuth meal consisting of 90 grams of bismuth subcarbonate suspended in 600 c.c. of fermented milk. The colon in all

these cases was ptosed to a degree corresponding with that of the ptosis of the lower border of the stomach. The appendix as an etiological factor could be excluded in five of the cases on account of a previous appendectomy. Six of the cases had operations and in all of these the positive *x*-ray findings were confirmed, as well as the position of the kidney. Post-operative radiographs demonstrated in every case the improved position of the stomach and colon. None of these patients had had any marked amount of post-operative abdominal pain, except in one or two cases, immediately after operation. Vomiting was present in only three cases and very serious in only one. Epigastric distress and a feeling of drag in this region was present in practically all and also loss of weight and neurasthenia. A history of constipation was present in all except one case in which radiographs demonstrated the colon to be empty in forty-eight hours. Evidences of colitis were found in three cases. The treatment of these cases was essentially medical, but in the operative cases the after medical treatment was apparently unnecessary except in two cases where neurasthenia was profound. The two principal indications were to relieve the drag and to cure or improve the constipation. The mechanical means for the former was abdominal support and position. The best support was the abdominal belt and a properly fitting abdominal corset. In the class of patients with a long narrow chest, narrow costal angle, and a large flaring pelvis, the abdominal belt reenforced by pads was alone advisable, as no corset would fit. It was essential that the belt or corset be put on with the patient in the proper position, which was on the back, with the hips elevated, the corset being laced up from below. While on the feet the support should not be removed. Radiographs in some of these patients a year or two after beginning treatment showed that the stomach had improved so much that they were almost prepared to state that the belt could be removed. Position would help this drag. The foot of the bed should be raised, slowly at first until the point of tolerance was reached, which was not over four or five inches and often less. The patients were instructed to lie down on the right side for at least one-half hour after each meal. Hydrochloric acid was probably the only drug that would be used for any length of time. The study of the individual diet and the selection of proper foodstuffs to correct the constipation was imperative. Instructions to the patient should always be written out in detail. Colon massage and vibration had given the best results in constipation, but must be systematic. The indications for operation were a severe grade of water trap stomach and a residue after five hours, provided that the symptoms had resisted treatment for four or five months, or showed a gradual steady loss in weight and strength, or could be readily demonstrated to have constant discomfort from this condition. It must always be remembered that this form of stomach might be temporary only and would return to normal position after rest and medical treatment. Appendectomy might be performed when in doubt, but should always be regarded as a conservative cure. The first operation was the important one; secondary operations were not so good in these neurasthenic patients.

**Radiographic Evidence of Gastrointestinal Stasis.**—Dr. Adoniram J. Quimby presented this paper and gave a lantern slide demonstration. He stated that he would show only the usual sites at which the bismuth meal was observed to stagnate and the slides would throw some light on one of the causes of this condition. The bismuth meal rarely met with resistance before reaching the lower end of the esophagus, except in diverticulum and pressure from neoplasm or stricture from deglutition of caustics. A few cases of spasm near the upper border of the sternum had, however, been reported. At the cardiac opening of the stomach a more or less permanent contraction was frequently observed, which in its earlier stages was purely spasmodic. As neoplasms also developed in this location whether independently or following the irritation produced in old cases of cardiac spasm, differential diagnosis was occasionally difficult. The next site at which a delay of the bismuth meal was observed was at the pylorus. The same causes were operative in producing stasis at the pylorus as those mentioned in connection with the cardia. Again stasis might occur at the junction of the first portion of the duodenum. Here and at each of the succeeding sites at which the bismuth meal was found retarded ptosis exerted an influence which it did not seem to exert in the upper portion of the digestive tract. Ptosis acted in two ways; the lumen of the gut was actually narrowed and in addition a sharp angle in the intestine was formed which resulted from the tension across the fibers of the suspensory ligament. The next point at which stasis was frequently noted was the duodenojujunal junction at which point another suspensory ligament of some size existed, and which offered considerable resistance to the downward tug of the ptosed organs so that it caused this part of the gut to be tightly drawn at an acute angle, interfering with the passage of its contents. From this point to the terminal ilium no suspensory ligaments of more solid texture than the rest of the mesentery were found and consequently, cases of stasis in the jejunum and the course of the ilium were probably not observed except when the lumen of the gut was decreased by external causes. In the terminal ilium all the causes of stasis previously mentioned were operative, and, in addition, the immediate effect of stasis in the subsequent parts of the bowel. In the ascending and transverse colon shaper angulations were frequently observed which it was impossible to change by placing the patient in any of the surgical positions, and it was his opinion that these angulations followed known hydraulic laws and caused most serious interference with the functions of the intestine at this point. This belief was strengthened by the theory of Holtznecht that the onward movement of the feces through the colon was not continuous but intermittent. The sigmoid was a point of even greater interest than any of those already mentioned. As was well known, it was much longer in proportion in infants than in adult life and it was an important factor in the causation of constipation in infancy and childhood. Stasis in the sigmoid naturally produced the same condition in the remainder of the colon. As this condition progressed there was not only interference with the muscular coats of the bowel, but a passive hyperemia developed which interfered with their nutrition and innervation so that in turn all the supports of the abdominal contents were subjected to undue stress during their development which was also a period of greater activity and indiscretion. After tracing the development of the condition known as splanchnoptosis, Dr. Quimby said that in the development of this condition one of the regions which had of late attracted attention was the terminal ilium. Arbuthnot Lane had mentioned a number of causes directly responsible for the stasis at this point, such as true Lane's kink, adhesions of the appendix to the ilium, stasis in the ascending colon interfering with the iliac contents through the ilio-cecal valve, adventitious adhesions such as Jackson's membrane, etc., post-operative adhesions and obstructions from extraneous pressure as from neoplasms. In advanced cases of ptosis one sometimes found the stomach sharply flexed upon itself and in such a state of atomy that it seemed unable to bring its contents to the pylorus, which remained fixed near its normal position, so that these patients showed gastric retention after many hours if kept in the erect position, but suffered comparatively little inconvenience in the prone or recumbent position. Occasionally he had observed remarkable activity on the part of stomachs which were well down in the pelvis. He had examined a number of patients in whom gastro-enteroptosis had advanced to a considerable degree and in whom redundant sigmoid, colonic angulations, and iliac stasis were present without serious inconvenience, but in a number of them disastrous results followed comparatively slight causes such as mental strain, shock, trauma, etc., which led to the belief that these conditions greatly lowered the vitality and decreased the ability of the individual to withstand undue strain.

# State Medical Licensing Boards.

## STATE MEDICAL EXAMINATION QUESTIONS.

Arkansas State Medical Board.

*May 14 and 15, 1912.*

(*Concluded from p. 368.*)

GYNECOLOGY.

1. Give the most common causes of sterility in the female.
2. Name the dangers of the use of the uterine sound.
3. Differentiate subinvolution, rectocele, pyosalpinx, cervicitis, metritis, vaginismus.
4. Describe the technic of catheterization.
5. How would you determine whether cancer of cervix is operable or not?
6. What may be revealed by digital vaginal examination?
7. Differential diagnosis of appendicitis and right tubo-ovarian disease?
8. Give symptoms of acute pelvic peritonitis.
9. Give diagnosis symptoms of carcinoma of the breast.
10. Mention three pathologic types of endometritis.

SURGERY.

1. What are the causes of ptosis and the remedial measures employed?
2. Give the indication and technic of operation for ligation of common carotid artery.
3. What surgical landmarks of the elbow-joint would aid you by their position in diagnosis between a fracture of the upper end of the radius and a posterior dislocation of the ulna?
4. Describe in detail the operation of lumbar puncture. What are the indications for this operation?
5. Describe amputation at the hip-joint. Give the method of inserting Wyeth's pins.
6. Give etiology, symptoms, and treatment of psoas abscess.
7. Describe the following tumors: keloid, papilloma, and epithelioma.
8. Define coxa vara; give causes and symptoms.
9. Give indications and contraindications for salvarsan (606) in treatment of syphilis. Technic of your method of administration.
10. Why do foreign substances such as bullets, splinters, pieces of glass, etc., cause suppuration when embedded in tissues?

HYGIENE.

1. Describe a thoroughly safe method of disposing of sewage in the absence of water-works.
2. Name the diseases carried by infected water.
3. Define epidemic, endemic, and pandemic diseases.
4. What precautions should every consumptive take to prevent spreading the infection?
5. What are the practical necessities of pure food and drug laws?
6. What are the effects of chronic alcoholism?
7. Give full directions for nursing a case of typhoid fever to prevent its extension.
8. Define disinfectant; germicide.
9. Give full directions for ventilating an ordinary bedroom.
10. What is the most common cause of blindness in young children, and how is it to be prevented?

## ANSWERS.

GYNECOLOGY.

1. The *most common causes of sterility in woman* are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix.

2. *Dangers of the use of the uterine sound* are: Sepsis, perforation of uterus, hemorrhage, and induction of abortion.

3. In *subinvolution*, there is a history of recent delivery, and the uterus is large and boggy.

In *rectocele* there is a hernia of the rectum into the vagina, covered by the mucous membrane of the posterior vaginal wall.

*Pyosalpinx* is accompanied with pain and tenderness over the affected part, made worse by vaginal examination; fever, and dysmenorrhea.

In *cervicitis*, the neck of the uterus is inflamed and sunken, and there is a glairy, tenacious discharge.

In *metritis*, the uterus is enlarged, tender, and there is a leucorrheal discharge thinner than is found in cervicitis.

*Vaginismus* is characterized by painful and spasmodic contraction of the vaginal orifice which renders coitus or vaginal examination painful or altogether impossible.

4. *Catheterization.* "The instrument should never be introduced by touch alone, but always by sight. The labia minora should be separated, and the vestibule cleansed with absorbent cotton saturated with an antiseptic solution. The instrument, preferably of glass, should be perfectly smooth, with no rough or cutting edges. It should be boiled, kept in an antiseptic solution, and previous to use should be washed with sterile water. It is then lubricated and passed upward and backward by very gentle pressure and without using any force." (Gould and Pyle's *Cyclopedia.*)

5. Cancer of the cervix is operable only when the disease is limited to the cervix; hence any extension is a contraindication to operation. The uterus must be freely movable.

6. A *digital vaginal examination* will show: (1) The condition of the perineum, whether torn or not; (2) the size, shape, dilatability, temperature, discharges (if any) of the vagina; (3) the presence of cystocele, rectocele, prolapsed uterus, or other abnormal conditions of vagina; (4) position, shape, size, consistence of cervix, with presence or absence of erosions, lacerations; (5) condition, shape, size, location, and mobility of uterus; (6) sometimes presence of abnormalities in tubes, and ovaries, and uterus (such as tumors, inflammations, etc.).

7.

| APPENDICITIS. | ADNEXAL INFLAMMATION. |
|---|---|
| 1. No previous local disturbances. | 1. Genitourinary functions previously disturbed. Usually a history of gonorrheal or puerperal infection. |
| 2. Chill usually absent. | 2. Chill may precede fever. |
| 3. Pain in right iliac region, sudden onset, acute, and not radiating to thighs. | 3. Gradual onset, pain dull, continuous, and radiating. |
| 4. Fever of variable degree. | 4. Fever often entirely absent. |
| 5. Muscular rigidity on right side of the abdomen. | 5. No muscular rigidity unless complicated by peritonitis. |
| 6. Inflammatory exudate about appendix three to five days after onset of symptoms. | 6. Inflammatory exudate in the pelvis felt by vaginal examination at the onset of the symptoms. |
| 7. Vaginal examination is rarely painful in appendicitis. | 7. Always painful in tuboovarian disease. |

—(Findley.)

8. ACUTE PELVIC PERITONITIS. *Symptoms:* "The pulse is first rapid, full, bounding; later, small, hard, wiry, or thready; in bad cases, soft and irregular. The temperature rises early, and continues more or less elevated. Often the onset is marked by rigors. Pains develop of a burning, cutting, darting, or boring nature. There is nausea, vomiting, constipation; sometimes diarrhea. When pus collections have formed, the symptoms are those of abscess. Pus may tend to open through vagina, bowel, bladder, or through the abdominal wall. *Physical signs:* The abdomen is early rigid. Afterwards it may be distended. Both legs are drawn up. The belly is tender or painful in its lower part. On bimanual examination, the vagina is hot and sensitive. When there is free fluid in the pelvis, an indistinct boggy fullness may be made out. When consolidation has taken place in it a hard mass like plaster-of-Paris is felt behind, and at the sides of the cervix; sometimes around it. In other cases, masses of serous fluid may be encysted, and are felt in the middle line pushing the uterus forward; sometimes in front of the uterus, when this organ has been retroverted; sometimes on either side behind the broad ligament. After an acute attack has passed off, various conditions are found, *e.g.*, thickenings, adhesions, displacement of uterus or appendages. There is usually considerable tenderness on examination." (Webster's *Diseases of Women.*)

9. The *diagnostic symptoms of carcinoma of the breast* are: A hard, irregular tumor in the breast; at first movable, later fixed and adherent to the breast or pectoral muscle; it is not clearly defined and limited; there is generally retraction of the nipple, and pain (often severe) is generally present; induration is evident, and the breast may be enlarged; the lymphatics in the axilla and above the clavicle may be found enlarged.

10. *Endometritis* may be: Glandular, interstitial, and mixed.

SURGERY.

1. *Ptosis* may be caused by paralysis of the motor oculi nerve, by injury to the levator palpebræ muscle, or by inflammation of the upper eyelid. *Treatment* consists in removing the cause, if possible; in removal of a piece of the skin of the upper lid; in the use of a lid elevator.

2. *Ligation of the common carotid artery is indicated* in: Wounds of common carotid, external carotid, internal carotid, and branches of external and internal carotid; aneurysm; and to limit the growth of inoperable tumors. The line of the common carotid artery is from the sternoclavicular articulation to midway between the angle of the jaw and the mastoid process, the patient's head being turned toward the opposite side. An incision three inches long is made along the anterior border of the sternomastoid muscle, the center of the incision being opposite the cricoid cartilage. In cutting the superficial fascia the external jugular vein must be avoided. The deep fascia is opened, the sternomastoid muscle is retracted outward,

and the omohyoid muscle is retracted downward; the carotid artery is located as it crosses the carotid tubercle, the descendens noni nerve is on the sheath of the artery. The sheath is opened at its inner side, the artery is freed from the sheath, and the needle is passed from without inward.

3. Normally, the tip of the olecranon process, in extension, is in a line with the two condyles; in semiflexion it lies below the line of the condyles. In dislocation of the ulna this relationship is changed; in fracture of the radius this relationship is not changed.

4. *Lumbar puncture* "is the operation for withdrawing cerebrospinal fluid from the subarachnoid space of the cord. It is employed as a means of diminishing cerebral pressure in hydrocephalus, cerebral tumor, uremia, and tuberculous meningitis, but in these cases it has proved of little or only of temporary therapeutic value. It may be of some service in cerebrospinal meningitis. The condition of the patient with a fracture of the base of the skull is sometimes temporarily improved by the operation. Pain is often temporarily relieved. In the performance of a brain operation the brain may bulge so that the dura cannot be sutured. Lumbar puncture makes suturing possible. Puncture is the preliminary step of spinal anesthesia. In some cases the examination of the fluid has been of great diagnostic value. . . . The back should be carefully sterilized and through asepsis must be preserved in every detail. The patient may lie on the right side with the left knee well drawn up, may lie prone with a pillow under the belly, or may sit in a chair with the body bent forward. The site of the intended puncture may be frozen with ethyl chloride, but no general anesthetic is required. A Pravaz syringe is employed. The needle, which should be three inches in length, is guarded by the surgeon's index-finger and the point is inserted one-half inch to the right of the median line and between the third and fourth lumbar vertebræ. It is pointed upward and a little inward under a spinous process. In a child the needle enters the canal at a depth of from two to three centimeters; in an adult, at a depth of from four to six centimeters. The fluid is permitted to fall drop after drop into a sterile test-tube." (DaCosta's *Surgery*.)

5. *Wyeth's pins, and hip amputation.* "The outer pin is inserted an inch and a half below and a little internal to the anterior superior spine of the ilium, and is brought out just back of the great trochanter. The inner pin is entered one inch below the level of the crotch and internal to the saphenous opening, and it emerges an inch and a half in front of the tuberosity of the ischium. A sterile cork is pushed on the end of each pin, to save the surgeon from wounding himself upon the sharp points. After the limb has been emptied of blood by holding it in a vertical position for five minutes and stroking it from the periphery toward the body, the constricting band is fastened about the limb above the pins. In the bloodless method of Wyeth after the passage of the pins and the application of the band of the Esmarch apparatus, the amputation is proceeded with. The hip is brought well over the edge of the table, a circular incision is made down to the deep fascia, six inches below the constricting band, and is joined by a logitudinal skin-cut reaching from the band to the level of the circular incision, and the cuff is reflected to the level of the lesser trochanter. The muscles are cut by a circular sweep at the level of the retracted cuff, the capsule of the hip-joint is opened freely, the cotyloid ligament is cut posteriorly, the thigh is bent upward, forward, and inward to dislocate the head of the bone, and, using the thigh as a handle, the round ligament is incised and the limb removed. After ligating the vessels and introducing drainage-tubes the flaps are sewn together vertically." (Da Costa's *Surgery*.)

6. Psoas abscess. "Chronic collections of tuberculous fluid, which form in the cellular substance of the loins, behind the peritoneum, and descend in the course of the psoas muscle. *Etiology.*—This disease arises generally from cold, strains, or falls, and from general debility, and not infrequently from spinal affections. *Symptoms.*—At the beginning there is little or no pain, no inflammation, nor is there febrile disturbance; but previous to the appearance of any other symptom the patient has an unaccountable feeling of weakness across the loins, accompanied by pains, usually giving no indication of the seat of the disease, and likely to be regarded as rheumatic. The tuberculous fluid is formed slowly and imperceptibly, and occasions, at first, no manifest swelling or fluctuation. When the lower dorsal or upper lumbar vertebræ are diseased, the pus enters the sheath of the psoas, or the substance of the muscle, and is firmly bound down in front by the fascia covering this muscle and the iliacus. The abscess proceeds as far as the tendon of the muscle by Poupart's ligament, where its further progress will probably be arrested. When it has attained considerable magnitude, it passes under Poupart's ligament, between the femoral vein and the symphysis pubis. The diagnosis is difficult when the abscess is unattended by an external tumor. The swelling takes place in various situations and assumes different aspects; it may appear beneath the femoral fascia, or it may descend as far as the knee and form a prominent swelling; sometimes it will make its way downward into the pelvis and occasion a swelling in the neighborhood of the anus, or it may appear in the vicinity of the vertebræ, or, again, it may make its way through the abdominal muscles. *Treatment.*—A psoas abscess should be opened, if possible, before it leaves the abdomen, just about Poupart's ligament, external to the line of the vessels. If it points at the inner side of the thigh, an incision may be made in that situation, in addition to the one above Poupart's ligament. Under antiseptic precautions, the sooner the abscess is opened, the better, for the abscess cavity is then smaller than if the surgeon waits until the fluid has burrowed its way into the thigh. Free drainage should be established from the groin to the lumbar region. Antiseptic dressings must be continued as long as there is discharge. General tonic and alterative treatment are indicated." (Gould and Pyle's *Cyclopedia*.)

7. *Keloid* is a skin tumor resulting from overgrowth of connective tissue; it generally arises from scar tissue.

*Papilloma* is a tumor consisting of hypertrophied papillæ of the skin, with connective tissue and blood-vessels; it has a covering of epithelium.

*Epithelioma* is a malignant tumor composed of epithelial and connective tissue cells; it begins on the surface and invades the underlying tissues.

8. *Coxa vara* is a condition in which the neck of the femur is horizontal, or even directed downwards. It is met with at two ages; in infants of three or four years of age, and due to rickets; in adolescents of thirteen to eighteen years, who have to stand much or carry heavy weights. Slipping down of the epiphysis is said to be a cause in some cases. The neck is bowed forward, and the trochanter is thrown backward, so that the leg is everted.

*Symptoms* begin with some pain in the hip and limping. The trochanter is raised above Nélaton's line, and there is marked rotation outwards of the limb. True shortening is present. The movement of external rotation is increased; flexion, abduction, and internal rotation are diminished, as the trochanter is stopped by the rim of the acetabulum. There is no swelling or tenderness, as in hip disease, or sliding of the head of the bone, as in congenital dislocation. (*Aids to Surgery*.)

9. *Salvarsan is indicated* in: "(*a*) Early cases of syphilis in which contagious manifestations are appearing in rapid succession, in spite of efficient mercurial medication. (*b*) Cases in which, for family or social reasons, it is of special importance to limit the production of infective material or cause the disappearance of symptoms in the shortest possible time. (*c*) Cases in which the symptoms are recalcitrant to the action of mercury, or in which, from idiosyncrasy, that drug cannot be exhibited in sufficient dose. (*d*) Cases of syphilophobia and syphilomania, whether showing symptoms or not; its psychic action in these instances being of greater importance than its therapeutic effect. (*e*) Very early cases of the sequelæ of the luetic infection, before organic changes have occurred."

*Salvarsan is contraindicated* in: "(*a*) Cases that are doing well, *i.e.* in which the disease is pursuing its normal mild course under ordinary medication. (*b*) Cases with serious organic lesions of the eyes, kidneys, heart, or other internal organs. (*c*) Cases with postsyphilitic or parasyphilitic disease of the internal organs, more especially of the nervous system." (*Progressive Medicine*.)

Salvarsan should be administered intravenously. The method is described by Hirsch as follows: "Two graduated glass containers of 250 c.c. capacity are used. Into one is poured 150 to 200 c.c. of sterile salvarsan solution. The other is filled with a like volume of sterile saline solution (made with sterile distilled water and chemically pure sodium chloride). The saline solution is allowed to flow out of the needle so as to expel all air from the tube. The stop-cock is now reversed, allowing the salvarsan solution to flow out of the needle, thereby expelling all air from its tubing. The stop-cock is now reversed to its former position, until the saline solution is running in a slow even stream from the needle. The desired site of puncture is selected on the arm or at the elbow, and the needle is gently pushed or thrust through the skin into the vein. Meanwhile the saline solution is continuously running from it. The needle is held at about an angle of 10 to 15 degrees to the skin surface, depending on the prominence and caliber of the vein. Care must be exercised not to push

the needle through both walls of the vein. This can be avoided by not introducing too long a surface of the needle into the tissues. The patient's arm having been carefully cleansed, a ligature in the form of an ordinary soft rubber catheter or tubing is tied around the middle of the arm, above the selected site of puncture, and the patient is requested to tighten the fist so as to make the superficial veins more prominent. Some prefer to expose the vein in all cases. As soon as the needle has entered the vein, the rubber ligature is released by an assistant, the stop-cock of the needle is reversed, and the salvarsan solution flows through the needle into the vein. Hence there is no danger of any salvarsan solution getting into the subcutaneous tissues. The intravenous injection must be given slowly, not less than ten minutes being spent in the process; and the solution must be quite warm when poured into the container so as to allow for its cooling when flowing into the apparatus; when it enters the vein, the solution should be about the temperature of the blood. An ideal intravenous injection is painless."

10. Microorganisms are introduced with the foreign body; and, at the same time, the trauma produced by the foreign body lowers the resistance of the tissues.

### HYGIENE.

1. "The pail system and the dry earth closet are the principal types of the dry methods of sewage removal. In the pail system the excreta are simply received in boxes or tanks, and these are emptied whenever necessary. In the dry-earth closet a receptacle containing dry earth is placed in the closet and about ½ kilogram of dry earth is thrown over each evacuation. The earth is a natural deodorizer and the mass remains inoffensive for a long time, the fecal matter being finally entirely disintegrated. A separate receptacle is supplied for the collection of the urine. This system is the least objectionable in such localities where a general water supply is not available, or where the climate is too severe to render a water-closet safe and serviceable. In the dry methods of removal the final disposal of the fecal matter is as fertilizer upon cultivated land." (Bergey's *Hygiene.*)

2. *Diseases carried by infected water:* Typhoid, cholera, dysentery, diarrhea, indigestion, goiter, intestinal worms, and lead poisoning.

3. A disease is said to be *endemic*, when it is found in a certain locality more or less constantly; it is said to be *epidemic*, when it affects a large part or the whole of a certain community; and it is called *pandemic* when it is prevalent over a very large portion of the continent at one time.

4. Consumptives should abstain from spitting anywhere except in a proper receptacle; the sputum should be disinfected or burnt; they should sneeze only in their handkerchiefs; they should abstain from kissing; their rooms should be free from carpets and hangings, and should be frequently cleaned and disinfected.

5 Pure food and drug laws should be framed with a view to protect the public, should be fair and broad in their intent and interpretation, should distinguish between fraud on the purchaser's health and fraud on his pocket, and should be impartially enforced. All goods "passed" under such laws should be so designated; goods should be labeled and their contents and weight or volume plainly stated.

6. *Chronic* alcoholism may produce dyspepsia, coated tongue, fetid breath, morning vomiting, vertigo, muscular weakness, bloated face, impaired will-power and memory, and blunted moral sense.

7. To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food.

8. A *disinfectant* is an agent which restrains infectious diseases by destroying or removing the microorganisms which cause them. A *germicide* is an agent which destroys bacteria and their germs.

9. The window and door should be opposite, and both should be left open whenever possible. The window should look out on the open, and not a court or air shaft. A board may be placed underneath the lower sash of the window, this will allow the entrance of fresh air at the junction of the sashes without causing any draught.

10. The most common cause of blindness in young children is ophthalmia due to the gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth.

### BULLETIN OF APPROACHING EXAMINATIONS

| STATE | NAME AND ADDRESS OF SECRETARY | PLACE AND DATE OF NEXT EXAMINATION† | |
|---|---|---|---|
| Alabama* | W. H. Sanders, Montgomery | Montgomery | July 8 |
| Arizona* | J. W. Thomas, Phoenix | Phoenix | April 7 |
| Arkansas | F. T. Murphy, Brinkley | Little Rock | May 13 |
| California* | C. B. Pinkham, 929 Butler Building, San Francisco | San Francisco | April 1 |
| Colorado | David A. Strickler, Empire Building, Denver | Denver | April 1 |
| Connecticut* | Chas. A. Tuttle, New Haven | New Haven | Mar. 11 |
| Delaware | J. H. Wilson, Dover | Dover | June 17 |
| Dist. of Col'ba | Geo. C. Ober, Washington | Washington | April 8 |
| Florida* | I. D. Fernandez, Jacksonville | Jacksonville | May 12 |

| Wyoming | A. B. Tonkin, Riverton | Cheyenne | March 5 |

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

**Primary Adenomata of Liver.**—H. C. Gordinier and H. R. Sawyer report a case of this condition possessing the following points of interest: (1) it presented the symptom complex of Hanot's hypertrophic biliary cirrhosis; (2) the study of the liver did not bear out the generally accepted view that multiple adenomata are always secondary to and in compensation for liver cirrhosis; (3) it showed the importance of recognizing the fact that symptoms identical with those produced by either the atrophic or the hypertrophic form of cirrhosis may take their origin from multiple adenomata.—*American Journal of the Medical Sciences.*

**Aberrant Thyroid Tumor from the Base of the Tongue.**—W. G. Howarth reports the case of a patient who complained of great difficulty in swallowing with occasional attacks of dyspnea. The tumor involved the base of the tongue in the middle line and was pressing against the lingual surface of the epiglottis. There had never been any symptoms of thyroid insufficiency. The thyroid in the neck was scarcely palpable, but at the time of operation, when a preliminary laryngotomy was performed, both lateral lobes were found to be present, though no trace of the isthmus could be detected. The section showed a fibrous capsule outside a layer of thyroid glandular tissue; the center of the tumor was made up of blood-clot.—*Proceedings of the Royal Society of Medicine.*

### MALIGNANT DISEASE OF THE TONGUE AND MOUTH.*

By ROBERT ABBE, M.D.,

NEW YORK.

SENIOR SURGEON TO ST. LUKE'S HOSPITAL.

THE subject I have chosen is of interest to the physician as well as the surgeon, to reconsider whether the status of treatment has changed in the last decade; whether new agents or methods of combating the dread disease have been added to our equipment, or whether theories or methods of treatment can better the condition of our patients.

The physician will have to differentiate several varieties of growths and ulcers of the tongue, lips, cheeks, gums, and palate, many of which are wholly innocent, but may later become malignant, and it is of extreme value to him to allay anxiety, or to direct his skill against present danger.

I shall make no attempt to elaborate the subject beyond a personal experience which furnishes ample material for discussion.

The basis of these remarks I have taken entirely from my private office note books which record every personal case in my lifetime. I have culled out of the records of only the past ten years such cases as bear on this subject. These I have subjected to personal study and shall present only my conclusions.

During these ten years, exclusive of hospital service, I have notes and illustrations of 40 cancers of the tongue, 15 leucoplakias, 27 sarcomas of the jaw and epuli, 40 sarcomas of the pharynx and tonsil, and carcinomas of mouth and cheeks, besides many tumors of the lips, palate, and buccal mucosa.

These ten years have seen arise hopes of newer remedies like *x*-ray, radium, and fulguration, to supplant caustics, cautery, and knife.

I have candidly refused to discard the knife whenever experience had shown its value—and believe it will be our sheet anchor indefinitely.

My work has been pursued with some hope but no illusions, and I am sure the ground I have gone over need not be gone over again. Whoever wishes to repeat the strain in this field will be thankful to be saved some doubts by my experiences. Goethe said: "Blest be the man who cures my doubts and gives me none of his."

The appeal of suffering in diseases of the mouth is quite equal to, if it does not exceed, the misery of diseased states in other parts of the body. The discomforts of eating and talking, the desire to conceal disease of the tongue, the suffering from salivation and pain make this field one of the greatest to one who wishes to be a benefactor.

*Paper read before the Practitioners Society, January 3, 1913.

At the same time it is surprising how many mouth conditions are not known of, by patients, until disease has far advanced; so few people look at their tongues or throats in a mirror until pain comes. It is quite common to discover an exostosis in the middle of the roof of the mouth, hard as ivory, which had existed for perhaps twenty years unknown to the patient until a sip of hot soup makes it sore by blistering it. Patients are often surprised by their physician first discovering advanced cancer inside the cheek, or on the tongue which had been growing for many months. It is not surprising then that both physician and patient desire to "take a chance" on its soon going away, and, as Butlin says, thereby "give it a chance to grow," until surgery is difficult.

It is fair to say that the diagnosis of benign from malignant tumors is not always easy at sight. There are frequent warty growths, papillomas of the tongue, or true warts of the lips, tongue, or inside of the cheek which simulate early cancer. Recently I saw a large wart on the roof of the mouth, which being identified by its mulberry-like surface, was permanently cured by one radium application. There will be seen sometimes small hard areas of induration associated with tongue irritation, which disappear with removal of a cause, but they are so rare that we may regard any hard spot in, or under the tongue, with suspicion.

Some fifteen years ago I excised a solid tumor the size of a medium olive, grown into the surface of the tongue, which has never come back. Dr. Ferguson and Dr. Hartley pronounced it angiosarcoma. It was encapsulated and had grown rapidly. This form is rare.

But the early epitheliomas and papillomas are the varieties most frequently seen and call for differentiation. The papillomas are raised, red and firm, with bases buried in the thick derma of the tongue quite like epitheliomas, but lacking in the infiltrating quality which can be felt when the base is pinched between the examining fingers. This quality is usually sufficient to decide the diagnosis. Yet sometimes removal of a small section of a papilloma will show microscopic changes beginning in the base, of true epithelial type. Such tumors usually come to the surgeon after they have been irritated by futile applications of nitrate of silver or caustics.

The question of whether a true wart is liable to alteration into cancer is of importance. It is a species of cant in our profession to repeat this statement generation after generation without challenge. But it is so rare to identify such changes, and the cases of persistent recurrence and removal of true papilloma, as in the vocal cord region, for forty years or more without alteration, throw such a doubt about the peril of cancerous degeneration that we may well regard the true papilloma of the mouth and tongue as benign.

I have seen several such that have recurred for several years without changing to cancer, which have been referred to me as tongue cancers and which have been instantly and permanently cured by one application of radium. This happy outcome does not happen when the growth is epithelioma.

I have illustrated in a colored plaster cast of such a large ulcerating growth of the tongue which I present for inspection, one case in my own experience, which represents an important border line type.

In the center of the middle surface of a man's tongue was a raised ulcer of the size of one's finger nail. It presented the appearance of early cancer, but being in an unusual situation and not seeming to be buried in the tongue tissue I diagnosed papilloma, and sent the case to Dr. Farquhar Curtis for corroboration before treatment. Dr. Curtis based his opinion of its non-malignancy on the absence of an infiltrating base. I cut out a section for Dr. Wood for report. He said: "Thickened epithelium with mitoses, either papilloma or epithelioma."

I applied radium for two hours and rapid cure followed, with no return after four years.

I am not yet convinced that there is much danger of warty growth undergoing malignant degeneration. I have never seen it occur in the warts of the skin, which even after years of chronic thickening and painful inflammation of the base, are immediately and permanently cured by radium, no matter how large they may be.

As illustrating this view, I may cite the case of the late Dr. X, who had for three years a vicious wart over the end joint of his middle examining finger. It had become so tender, cracked, and persistent that he had been advised by able surgeons to have it excised on account of its probably having undergone change to epithelioma. He appealed to me and sat one hour in my office with one radium cell held on the growth. It promptly melted away without scar, and for three years never came back.

I venture to quote this as an up-to-date opinion of eminent surgeons regarding a "possible change" which I have never seen occur. If the growth had been epithelioma it would have left a scar, but as it was only irritated papilloma, a normal skin remained. Such history applies perfectly to papilloma of the tongue. I show you some excellent illustrations, and they are easily identified and readily cured by radium, which is not true of epitheliomas.

I will speak briefly of malignant growths of the gum and lower jaw. These come to the notice of the physician as either red, bleeding, granulation-like growths between the teeth and spreading on the gum, or, as firm, dusky growths of the alveolar gum, growing from the bone itself. The former are mostly epithelioma, but in one case I found the small bleeding growth pathologically was giant cell sarcoma, which recurred, and then suffered the usual fate of cure by radium.

The lesser types of epithelioma, often of great annoyance by bleeding to the tooth brush and painful to touch, are easily cured by radium without sacrificing the teeth, but when advanced in size are only to be treated by excision and radiumizing the base, which results in permanent cure.

I have had twenty-seven cases of giant cell sarcoma and epithelioma of the jaw; one sarcoma with extensive bone destruction, which I have once illustrated before this society and again tonight show the patient well, after eight years.

I have demonstrated (MEDICAL RECORD, August 27, 1904) that radium is a specific cure for pure giant-cell growths, and, unless there is a preponderance of spindle cells or fibrous tissue in the tumor I have no reason to alter this view. If we were to apply radium after excision of these growths there might be some question as to which of the two acts had wrought the cure; but in numerous cases which I have brought under the test of radium without other surgery and obtained permanency of cure, we have illustrated its unique action unaided.

Now let us consider true cancer of the tongue in the grave form in which it is so often presented to us. We may speak of it as the inoperable form. Every surgeon is guilty of operating on such cases. Hopeless as far as radical cure is concerned but sometimes worthy as far as relief from present distress. Also, perchance, worthy from a psychological point of view, as calling forth what the late Dr. Hammond called "the exhilarating sentiment of hope."

I refer to that large class where half the tongue is invaded, where the surface is broken down and opened up as a foul ulcer, and where numerous submaxillary or cervical lymphatics have absorbed the poison. Grant that operative surgery is refused by doctor or patient, have we any help in sight?

Locally, solutions of carbolic, chromic, or other purifying acids help materially in keeping the ulcer clean, but in no other way. Fulguration I have tried with no other than destructive effect, as far as appears in my limited use of it.

The Röntgen ray I have often tried, but the difficulty of its efficient application is usually insuperable. Yet it has undoubted value and retards growth. Radium I have given much consideration to. It is the most easily applied and acts somewhat like Röntgen ray; yet after assiduous and conscientious trial I would disclaim any permanent value in its use. From its undisputed curative effect on the same type of disease on the skin in early stages we had reason to hope for help in this agent.

Of more interest is it to ask, have we been able to prove it of any value whatever?

I have studied a large number of tongue cancers of the "explosive" type (to adopt a word dignified by the usage of Sir James Paget as applied to sebaceous cysts when they become inflamed and degenerate into cancer, the "explosive wens").

When the tongue cancer reaches the stage of a foul excavated furrow along the half tongue, with a heaped up mass of new growth about it, looking like an overcooked sausage which has burst its skin, we have reached a point in the patient's endurance which is about intolerable. Nothing known to surgery has heretofore altered or improved this condition. In many such cases I have eagerly watched the effect of strong radium. A few such have been referred to me by Dr. Bull, Dr. Blake, and Dr. Brewer and others who have watched and corroborated this result, namely, that the mass often begins to shrink in two weeks until the ulcer is reduced to a half or quarter of its size, and the massive tongue shrinks and becomes clean. In the substance of the tongue can usually now be felt one or two hard masses like primitive cancer spots around which a fierce inflammatory or bacterial warfare has waged, which had been checked by radiumization, leaving the original cancer unaffected. Practically it seems to be unaffected, because it soon takes on renewed growth, like the rallying of any battling giant, unconquered in the

end. Even the submaxillary lymphatics usually take part in the shrinkage, only to light up again after six weeks or two months.

So uniform has this action followed that I have been inclined to attribute it to a temporary control of bacterial infection, either by the specific bactericidal power of the agent or by the hyperemia called out by the intense play of electrons in the tissue.

If we could only go a little further in these cases with radium or find some new agent to take up the battle at this point, like reinforcements of fresh troops at a decisive point in battle, we would be nearer victory. But increase in use of radium now becomes too painful, whereas at first it allays pain like an anodyne. We must therefore wait on further experiments and offer only this much for study and hope.

But science is not easily downed. Consider the early stage of cancer, for one cannot draw a sharp line between the epithelioma and cancer.' The tongue is like the skin. Its layers take on the same morbid action. Epithelial thickenings of the squamous cells are true leucoplakia, such as we have seen to-night—continued irritation carries overgrowth into the papillary layers and we have epitheliomata, or, prolonged into the tongue, we have cancer.

It is in the first stage that radium will conquer all cutaneous keratoses. In the second or epithelioma it is equally potent. Will the same benefits occur on the wet surfaces of the mouth? To put conclusions first and demonstration later, I would say "possibly yes."

But no one yet has known the right dosage or method of using this agent, so that excepting in leucoplakia and thin underlying epithelioma one cannot yet show cures, but in leucoplakia it seems to be the only known efficient remedy. Of leucoplakias I have shown you good illustrations. I have studied my notes of about fifteen such cases.

Some years ago I showed to Mr. Butlin some colored casts which excited his greatest hope. He said, as every surgeon knows, that he had never found anything to affect them. Even shaving them off, caustics or acids or actual cautery were only temporary measures and produced worse scars. He said he would welcome as a benefaction the relief by radium. I may say that, properly applied, this agent can cure many of them and heal the associated epithelial hardening and ulcers that are usually present. It requires patience, but the end justifies the time. I speak of time because I have found that one or two well thought out applications, with a delay of at least two or three months, give by far the best results. On the other hand, the use of weak specimens, applied week after week, produce a cumulative and hurtful effect and prevent the observer from knowing what he may have accomplished.

The growths of cancer inside the cheek are extremely difficult to affect unless they be in the leucoplakia stage. Usually they grow midway in the cheek where the mucous membrane is of the thin epithelial type with little underlying dermal structure, and have a fumugating aspect often based on ture. Often they are based on the buccinator muscles into which they penetrate. It is utterly useless to expect radium to follow into such a base.

I show you illustrations of several such cases which incidentally demonstrate the causes of their growth. With one exception they have been exactly located where the victim had held his tobacco quid for years. The exception was a woman whose rough tooth had irritated the cheek. You have seen the patient to-night. The disease had involved also the gum and jaw. Dr. Bull sent her to me as inoperable in that stage and wished me to try radium. For one month the disease melted away to one-third, as if it had been a wart. I then excised the cheek and jaw because the disease in the bone would not yield. The result has been a perfect condition of health for five years.

How much the preliminary play of radium upon the tissues had to do with its permanent absence one cannot say, but it seems more often than not that there is some value in this association.

I would like to say a word about the causation of malignant disease of the mouth. Sarcoma, of the round or spindle cell type, is apparently congenital in origin, though long latent, and may best be cut out. Even so grave a case as I have shown you to-night of tonsil, pharyngeal, and cervical tissues has remained in perfect health for five years with no recurrence after excision.

But carcinoma is always the result of irritation, either by a tooth, a dental plate, tartar, a pipe stem, or tobacco.

The charge against nicotine is the most serious in the calendar. It is extremely rare to question a patient with advanced cancer of the mouth and not find that he has been a severe smoker or has chewed tobacco. If the question is answered evasively, or if he admits only gentle use of tobacco, his wife will usually come to your rescue and say that he either puts in a little chewing tobacco when he rises and takes a little out when he goes to bed, or that he smokes pipes or cigars habitually. This close relation with nicotine was emphasized by Butlin and has been widely believed in. I find complete corroboration in my own experience and have come to regard excessive and continuous use of nicotine as a great risk to susceptible tissues. It is usually after twenty or thirty years that the beginning of an epithelioma shows and insidiously advances. Most often it starts either at the contact points of the pipe, or streams of hot smoke on the tongue, or in the gutters where the nicotine lies in the mouth or where the quid rests between cheek and gum.

"Smokers' tongue" is a legitimate name for this ill-starred malady. One of the most threatening epitheliomas of the gum which I was fortunate enough to cure by radium, was in a young lady who for years had been an inveterate smoker of cigarettes. The cast I show you.

I have no desire to antagonize the social custom of smoking in moderation, but it is our duty to declare the menace of tobacco as a cause of most cancers of the mouth. When the first spot of leucoplakia comes it is wiser to stop the use of tobacco at once and forever.

When the inside of the cheek is extensively involved by cancer it is still possible to excise part of the cheek and expect to cure, as in the case shown to-night, but it is necessary to excise half the lower jaw in order to give free play in eating and to obtain enough sound tissue to close the defect. The cosmetic effect of this seemingly mutilating operation is remarkably good and the danger is almost nothing.

The object of this paper will have been accomplished if I have shown that:

Thorough surgery is still the supreme reliance in eradication of malignant disease of the mouth and early resort to it, is the patient's chief hope of cure.

Radium has many interesting conquests in this field, but in advanced cases of cancer its good effect is transient; in giant-cell sarcoma it is a specific cure.

The vicious causative effect of tobacco in the mouth is demonstrated.

Leucoplakia has no curative remedy unless it be radium.

13 West Fiftieth Street.

# OCCUPATION NEUROSES;*

## THEIR TRUE NATURE AND TREATMENT.

By TOM A. WILLIAMS, M.B., C.M. (Edin.).

WASHINGTON, D. C.

MEMB. CORRESP. SOCS. OF PSYCHOL. AND NEUROL., PARIS, ETC., NEUROLOGIST TO EPIPHANY DISPENSARY.

The term neurosis concerning occupational disabilities is a misnomer; for disorders of occupation to which this name has been given are in reality psychodynamic inhibitions or disorders in the habitual series of coordinated associations gained by education in some art. A want of harmony in the controlling of the mechanism is the fault. Hence the disharmony is always psychological. This is easily proved by the fact that the neuromuscular apparatus which fails to perform a particular occupational act can quite well accomplish any other act, and this by means of the same muscles, nerves, and brain areas. Hence there fall to the ground the interpretations of Hartenberg that hypotonia is the efficient cause of the professional dyskinesias attributed to neurosis. Nor can we except Kouindjy's explanation of an ataxia, which he believes because of the favorable effects of reeducation. Neuritis is often diagnosed but only by those ignorant of clinical neurology. Hypotonia or ataxia, when present, is a mere secondary effect of a primitive dyskinesia induced by a disharmony which has originated ideationally, although the mechanism through which it occurs is largely emotional.

The following considerations are explanatory: The induction of emotions by ideas is most clearly shown in a more acute form than occurs during the steady pursuit of an occupation. We find it best illustrated in the psychogenetic effects of accidents and the maintenance of these by the patient's own painful ruminations thereupon through what amounts to chronic fear and its effects upon the internal secretions.

The Emotion Excited by an Injury as a Perturber of the Apparatus of Internal Secretion.—An accident short of lesion may create in a susceptible person so great a fear as to cause a sudden increase of secretion by the thyroid gland. The recent researches of Crile have shown that this occurs almost constantly in patients with hyperthyroidism when they are frightened by the prospects of an operation. It occurs also in these subjects as a result of anxiety or unusual excitement. Crile believes that the thyroid gland is an organ by means of which there is rapidly available a store of an activating substance for the use of the neuromuscular apparatus when there is special need of its greatest power. Such an occasion is presented by the need for escape from danger. As the preservation of the species in locomotory animals may depend upon capacity to respond suddenly with the maximum of vigor against impending danger, there has developed through the long course of phylogeny this special organ of storing and rapidly setting free when required such a substance as the thyroid juice. But it would be a mistake to confine the need for the greater activation of the gland to physical escape from danger in the crude sense. In the higher animals life is no longer regulated by experiences purely phylogenetic, by the instincts. It is in the main controlled by ontogenetic incidents which we call experience and which modify the reactions in fashions incalculably complex. The determinators of these modifications we call association of ideas. Now, quite apart from the fear of bodily harm, there is a vast series of possible events which man seeks to avoid and which he apprehends as dangers from which to escape. It is reasonable to believe that psychological situations of this kind are capable of reflexly demanding the hyperactivation afforded by the thyroid juice. That is, fear from any source may create a temporary hyperthyroidism. But that the thyroid secretion is not the only one modified by emotion has recently been shown by a brilliant research of Cannon. He has shown that the emotion of fear in animals is capable of stimulating the flow of adrenal secretion. He demonstrated that in frightened animals the blood from the adrenal vein is so rich in adrenal substance as to be capable of inhibiting peristalsis in an isolated strip of intestinal muscle. This is due to the presence of the adrenal substance in appreciable amount, since it requires contact of the latter with the intestinal strip in a one millionth solution at least to inhibit peristalsis. We knew that the emotion of fear could inhibit gastric secretion; and Pawlow has shown that certain emotions of anticipatory joy can induce a flow of this secretion.

While it lasts the fear state presents marked physical symptoms. It does so through the intervention of the automatic nervous system, which cannot be controlled directly by volition except in rare cases and those only after much practice. One such case I saw in Philadelphia recently with Dr. J. Madison Taylor. The man in question, an athlete, had devoted much attention to control of his reactions. He is able to provoke at will the pilomotor reflex which produces the goose-skin appearance. He claims too that he can modify the rate of his pulse, but he did not succeed in demonstrating this clearly to me. He is able also to bring tears to his eyes by purely psychological means. Careful analysis shows that none of these reactions occur from pure willing. To produce them he has to assume a peculiar emotional state, which he describes as one of mystery. His introspection of this is not clear enough for one to say that it is not a feeling of horror. He thinks it is not, because it is rather pleasant, but the pleasure may be that of accomplishing something for which he strives. The analysis need not further detain us; for I quote the case only to draw attention to the impossibility of affecting the automatic nervous system by direct volition and to show the need of the intermediary of emotion for provoking autonomic reaction. The above case may be compared with the simpler one described by Babinski, and which I observed in Paris in 1907. This timorous young girl without practice in control was so apprehensive of the pin scratch used to elicit

*Read before the Section of Industrial Diseases, International Congress of Hygiene and Demography, Washington, September 24, 1912.

the plantar reflex that she involuntarily drew up foot and leg at the approach of the pin, and then occurred pilomotor contraction upon the skin over the upper and outer part of the thigh overlying the muscles which contract in the defense reaction when one strokes the sole (reflex of tensor fasciæ latæ). The patient could not control this response in any way; and its strict localization is unlike that of the preceding case, in which the goose skin was general when it came at all. Of course, these cases are somewhat peculiar but horripilation is a very common reaction to alarm.

Other common consequences are alteration of pulse rate and pressure: the frequecy may become more or less than normal and the pressure may be raised or lowered. Perhaps these differences depend upon the neurological type, or they may be functions of the varying responsiveness of the ductless glands in various individuals or at different times. Upon the digestion, the effects of alarm are well-known to be poor appetite and constipation with all their accompaniments. Upon the respiration, fear acts by a complete arrest followed by exaltation, or mere shallowing may ensue. It is a consequence of the inhibition of muscular activity known as fear-paralysis. This may be regarded as a phylogenetic mechanism for stabilizing an individual preparatory to efficient action. The effect of terror upon the flow of urine and control of the bladder needs only mention. Even the ancients knew, too, how fear arrested the sexual functions.

But the autonomic modifications of secretions soon cease as the fear shock of the accident fades; and in a few days at most the animal experimented upon or the human being insulted resumes stable equilibrium.

Psychogenetic Factors in Modifying Ideas, Feelings and Acts.—But the benign eventuality is often interfered with in human beings by the property they possess of reviving in memory the ideas which clothe situations with horror, apprehension, anxiety. Especially prone to this damaging sequence are persons whose imagination has been made rampant by the cultivation of the credulous fears of childhood: their fear reaction to that which they do not understand is a dominant one, and they are easily beset by an idea linked with fear. The commonest of the fears which result from accident or injury is that of bodily harm. It is very hard for a person of this type, when ignorant of his own structure and functions, to shake off the foreboding created by an impressive catastrophe; and it must not be forgotten that what others regard as trifling the victim may look up as catastrophic, judged by its possible effect on him. Prepossession by the idea of one's own disability is an inevitable consequence. This leads to abstraction from and inattention to the affairs of ordinary life, which, if not trifling by comparison in the patient's mind at least, cannot claim the attention properly needed. Hence ensues the well-known diminution of the capacity to think, work or take part in social life. This incapacity, when the patient becomes aware of it, leads him to still further accentuate the result of his injury and thus to augment his alarm about his health. Thus is constituted the vicious circle of hypochondria. Even a nosophobia may ensue, such as the fear of lost manhood, insanity, paralysis. Alarm at this impending disaster must, of course, be distinguished from the primary alarm due to the accident itself.

The next step in the drama is the reaction against the actual absence of physical signs of injury and the reassurances of medical men. This takes the form of an unconscious search by the patient in ratification of his belief that he is indeed damaged. Hence arises the familiar exaggerations and falsifications of symptoms. These are made in perfect good faith and honest belief, but they lead to the simulation of disease pictures previously in mind or acquired in the course of the disorder. It is only after the patient begins to be convinced in his heart that he is mistaken that there ensues the deliberate self-deception of the desperate effort to preserve the respect of himself and his friends which he feels he would lose by admitting the absence of physical disorder after all.

By this mechanism may spring what Brissaud called sinistrosis. Even a favorable settlement of a law suit may not remove this attitude. Only skilful psychotherapy will do so; and in severe cases considerable time must be allowed to wear down the sinister habit of mind.*

This mechanism was clearly illustrated in the case of sinistrosis which I fully reported to the International Congress of Industrial Accidents at Rome, 1909.† The rapidity of the success of the treatment in this and other cases is due to the thoroughness of the analysis which leads to the comprehension as above described. This leads to the description of rational psychomotor discipline, by which the patient is enabled to reeducate himself toward getting rid of dyskinesis which is in reality a dysboulia. In the occupational psychoses, for so they are, the mechanism is entirely similar, as is well seen in the case which follows:

Case I.—F. W., aged thirty, a telegraph operator, complained of cramping of the wrist and hand while using the Morse sender, typewriter, or the pen. Cramp sometimes occurs upon lifting a cup to drink, but only if he thinks of it. It occurs also upon brushing his teeth; but only those on the right side. It does not occur upon lifting up articles, unless he uses the fingers alone, when cramp may occur; but he can wind his watch, button his coat and collar and perform other ordinary acts without cramping. The movements consist of a flexing of the wrist when using the Morse key; an extension of the ulnar fingers when using the typewriter; a rigidity of the wrist when brushing his teeth; a giving way and radial rotation of the wrist on lifting a cup to his mouth; a rigidity of the whole arm when attempting to write. He is completely incapacitated from his usual work, but is able to address envelopes in pencil in the rigid fashion mentioned. The personal and family history were unimportant except that he had a nervous sister and was disappointed that he could not follow his father's profession of medicine, and had to work from boyhood. He neither drank nor smoked.

*The mechanism has been discussed at greater length illustrated by cases in: "The Psychic Effects of Accidents," *Monthly Cyclopedia*, November and December, 1912; *see also*, "The Import of Recent Work on Hysteria," *J. A. M. A.*, December 21, 1912; "Ten Cases of Hysteria Successfully Treated Without Minute Psychoanalyses," *Washington Medical Annals*, January, 1912; *Post Graduate*, June, 1912. Psychological mechanisms are described in the causation of similarly induced disorders in children, where their status is much simpler in Genesis of Hysterical Obsession, Medical Record, March, 1910; "Juvenile Psychasthenia," *American Journal of the Medical Sciences*, December, 1912. *See also* author's writings in the *Journal of Abnormal Psychology*, especially June, 1910.

†See Medical Record, April, 1909.

Although ambitious, he does not think that telegraphing was his forte, for though he had tried hard enough, others with less education did better. He had not realized this, however, until he was too old to easily find something else which paid as well. Perhaps he had found learning harder than most people, because he tried to learn at night while working as a clerk in the daytime. Even although ten years ago, after falling from a bicycle, dislocating his shoulder, he had worked in pain for five weeks before reduction was made, no disability had followed (not, however, at the key, but writing). He had not learned the Morse key in the usual way of the lads who pick it up as office boys and evolve into operators; for he began intentionally to learn when he entered an office at fourteen, and after four years could send forty to forty-five words per minute steadily with few mistakes. The cramp occured suddenly six years ago with "a kind of loss of use of the wrist, which would go up in the air while he was using the keys." At the same time the hand would flex. At the period when this ocurred he had been sending in the daytime for a stock broker from 9.30 A.M to 4 P.M.; whereas formerly he had never used the key for more than three or four hours, and that in the evenings. The stockbroker's work had to be done quickly and he felt it a strain; but he liked it in spite of its arduousness, for it did not seem to interfere with his health, although he had to eat lunch in the few minutes he could snatch at his desk. His only worry before the cramp occurred was the fear of not being able to do his work and of losing his position. Just before his disability began he had found that he was not making his letters correctly, and could not go fast enough for the work. He had to give up his position in about ten weeks after the occurrence of the cramp. Physical examination was otherwise negative except for an exaggeration of the deep reflexes.

This summary analysis must be compared with and interpreted in the light of those I have published in *The Journal of Neurology and Psychiatry, Leipsic,* 1912, No. 19. There, three cases of writer's cramp of different complexity are fully presented, and the method of management which led to their recovery is described and the principles thereof are set forth. They illustrate occupational neurosis as follows:

Case II.—A paymaster was obliged to sign over 200 checks a day. After an attack of "grippe," his signature had become a little uncertain, and one day it was refused by the bank. Dread of losing his position further augmented his difficulty; but he consulted me early, and one interview placed him in the way of cure after a few weeks' absence from work. His hardly legible scrawl at that time contrasts sharply with the bold and clear signature two and a half years later. The steps in the treatment were: (1) Discovery of the cause; (2) removal of the besetment, and (3) correction of the awkward position of the hands and the excessive rigidity of the muscles of the arm. This last was accomplished by gymnastics designed to give free movements, and by the frequent practice of free writing in a smooth, large, round hand, a little at a time.

Case III.—A woman had always disliked correspondence, and in consequence wrote very rapidly. During a time of domestic stress and anxiety on account of sickenss she was particularly impatient of the Christmas letters she had to write; and the cramp ensued. When I saw her two and a half years later, however, there was no marked fear-affect nor insistent desire to recover. But in about three months she gradually became able to write a normal hand without difficulty, as a result of graduated exercises made possible by freeing her mind from the besetment which produced the cramp when she attempted to write.

Case IV.—Singers' cramp and pen paralysis in a psychasthenic young woman. At the age of nineteen she received, after a concert, an anonymous letter which created shame when she sang in public thereafter. Her anxiety to be a successful singer, in conflict with this shame, produced a pharyngeal cramp, in consequence of which she had to give up singing for some years. Fear of laryngeal tuberculosis also played a part in this. Some years later a period of stress and poor health, combined with hyperconscientious efforts to do full credit to a difficult clerical post, led to writer's cramp. She was sent to me two years later after various unsuccessful medical and orthopedic attempts had been made to cure her. She was in despair at being unable to write, as she had to make her living, and although she had persevered she could not face an audience in solo, so that her earnings as a singer were insignificant. After six months of most arduous treatment she became able to write perfectly with both left and right hands, and the singing cramp was greatly improved. She has already taken a clerical position and a choir position once more. In this case the chief difficulty was to overcome the patient's false belief in a physical disease, first in the hand, then in the shoulder, later in the constitutional state due to a hypothetical tape-worm, and finally belief in a cerebral defect of neurasthenic type not psychological in mechanism. Eventual success in removing these beliefs led to the fruitful practice of gymnastic and caligraphic exercises, which before that had only aggravated her disability. The patient has since relapsed, having become careless regarding psychomotor discipline.

These cases clearly show the prepossession of the patients by the interpretation. This notion breeds anxiety regarding capacity to perform the task required, whether the act be writing or singing or what not. The nervous erethism of the anxious state is concentrated upon the apparatus required for performing the desired act of occupation. In this way there is induced the state known to golfers as "pressing," and seen familiarly in the stammering movements of those who are apprehensive under unusual mental stress in the performance of an act. Physiologically there occurs an involuntary innervation, lacking in proper coordination, mainly of the muscles about to perform the desired act. Instead of being in a state of tonic relaxation, the normal physiological one, they are already beginning to contract before the voluntary inception of the professional act. Both agonists and antagonists may contract irrespectively of one another. The condition is quasivolitional, as it is contingent upon the mental processes preliminary to the occupational act. Its incoherence is due to emotion, and the emotion, fear, is due to the idea that because of a physical disorder the act cannot be performed. This idea has arisen in various ways, as shown by the cases.

Cramp Neurosis is a Tic.—When occupational neurosis is dyskinetic in type, as in the cases cited, the cause of the disability is in reality the preemption of the muscles required in the act by a

tonic tic. It is ideational in origin, and conforms in every way to the well-known definition of Janet into which I need not enter here, as I discuss it in the memoir cited and in the *Journal of Abnormal Psychology,* September, 1912. But when there is no question of dyskinesis in an occupational psychosis the mechanism is essentially the same. For tic is merely a motor obsession contingent upon the idea of certain situations within or without the body. Pure besetment without motor expression is essentially the same in a psychological sense, as so clearly shown by Janet, and neither of these manifestations is ever unaccompanied by phobia or angst. So much so that some have regarded anxiety as the genetic factor of obessions. The clinical evidence that this is not so is abundant. That it is the notion of the situation in the patient's mind which is the determinant of the emotional reaction of his body is shown by a series of analyses of children made by the writer before the American Psychopathological Association, May, 1912, as well as in a theoretical discussion with casuistical illustration (*Journal of Abnormal Psychology,* July, 1910).

Therapeutic Errors Contingent Upon the Term Neurosis.—It is this state of obsession, expressing itself in the fear of one's occupation, which has received the name of neurosis so unfortunately; for the name leads to the idea of therapeutic intervention toward the lower neurones, such as their stimulation by strychnine and other drugs believed to be tonic in effect; such as by giving douches to arouse the nervous system; by attempts to improve nutrition through massage, exercise, more nourishing food: by the imposition of rest on the supposition that there is exhaustion of the nervous system; by prescription of change of scene, under the idea that the patient's balance will be thereby restored. These measures, excellent enough when indicated, are quite beside the mark in the affection we are considering.

The essential preliminary to treatment is the getting rid of the genetic idea. But before this is done the patient must be thoroughly convinced of the fact that it is this idea that produces the disability and that his previous belief that the disability is of physical origin whether of muscle, nerve or brain, is utterly erroneous. In other words he must clearly comprehend the psychodynamic genesis of his condition. The second step is for him to reacquire control of the psychomotor mechanism required in his occupational acts. This can only be attained by practice. In proportion to the length of time the perverted kinesis has obtained, these efforts to rectify it are difficult and prolonged. Thus, the naval paymaster who had been incapacitated only a few weeks was restored in less than a month, after one interview. The woman who had practically ceased writing for two and a half years required four treatments and about four months of practice before she could again write freely. The young woman with the multiple professional cramps required six months of the most arduous discipline and frequent consultations before she could again write with the right hand and sing without cramp of the throat. In the cases of numerous telegraphers I have studied, no treatment at all was undertaken, because, in part, of the long standing of their condition; but mainly because the tiring work of a telegrapher does not leave enough energy for the arduous discipline required for reeducating the mechanism of the professional act so complex, delicate and exacting as the use of the Morse key.

Theoretically it is clear, and practically my cases show that there is only one direct therapeutic means for them. That may be summed up as psychotherapy. Of course the effort demanded in a psychotherapeutic education requires for its best fruit a well-nourished nervous system, and the patient's hygiene must, therefore, be rectified when defective; but that is only a help and not a cure. The same consideration applies to prophylaxis. It is, of course, desirable that workers should be well nourished and that fatigue should be minimized; but this in itself will not prevent occupational neurosis if the ideational seeds are not prevented from germinating in the minds of the workers.

1705 N Street.

---

## THE MUNICIPAL CLINIC OF SAN FRANCISCO.

By JULIUS ROSENSTIRN, M.D.,

SAN FRANCISCO, CAL.

CHIEF SURGEON, MT. ZION HOSPITAL, CHAIRMAN ADVISORY COMMISSION, MUNICIPAL CLINIC.

In the latter part of 1902 a report on the matter of a restricted area for houses of prostitution was brought up before the police commissioners of the city and county of San Francisco. Through the years following nothing more than a discussion came of this report, which embodied the various methods employed in different cities of the world for the reglementation of prostitutes.

After the fire of 1906, and upon the proposal of its committee on health, pure food and tenement legislation, the Civic League of San Francisco, an organization consisting of some eighty-seven improvement clubs from all parts of the city, took up the matter of the general reglementation of prostitution and the desirability of enforced medical examinations. The work was referred to the joint committees (on education and public morals, Dr. G. Frink, chairman), and to the committee on public health, pure food and tenement legislation (Dr. Julius Rosenstirn, chairman).

A new report, based on a voluminous correspondence with the authorities of the various cities of this country and Europe, regarding their methods of reglementation of prostitution and their conclusions, was worked out by Dr. Frink, and it presented the recommendation that measures be at once taken for the proper medical examination and segregation of all unfortunate women engaged in this mode of life.

For several years fruitless efforts were made by representatives of the Civic League to have the authorities of San Francisco put these measures into effect.

In 1910 at last, upon the urging of and together with the Civic League, whose representative I had the honor to be, the Board of Health arranged a series of joint meetings of their own members, the State Board of Health, and a representative committee of clergymen of all denominations, for the consideration of the actual taking up of this work.

Finally, at a special meeting of the Department of Public Health of the city and county of San Francisco, held February 9, 1911, regulations were enacted of which the following is the preamble:

"In an effort to prevent the promiscuous dissemination of infection through the medium of venereal diseases, which class of diseases is included under the heading of communicable diseases, to minimize as far as it may be possible the dan-

gers arising from these loathsome maladies, and to that end to exercise an intelligent and systematic medical supervision over that class of individuals who through the nature of their habits render possible the spread of this class of diseases the Board of Health hereby enacts the following regulations with reference thereto—"

Briefly, these regulations then prescribed a certain circumscribed area in which houses of prostitution could be tolerated, the establishment of a clinic properly equipped with a suitable staff, medical and clerical, for the examination of women engaged in the practice of prostitution, specifying the period of time that may elapse between each examination and defining the duties of the police as ex-officio sanitary officers.

An Advisory Committee, of which I had the honor to be named chairman, was appointed to take full charge of the administration of the clinic and its finances, under the supervision of the Board of Health, its president being one of the members of the committee.

In compliance with these regulations, premises were secured at 682 Commercial Street, and opened March 21, 1911. About October of that year, through an order of the Superior Court, the McCarthy appointees on the Board of Health were removed from their positions, and the former appointees of Mayor Taylor, of the previous administration, reinstated. The reconstructed Board of Health did not care to continue its association with the Municipal Clinic, and the institution has since been continued independently under the sole control of the advisory committee, with the sanction of the mayor, the board of supervisors, and the police commission.

At the present time the Municipal Clinic is operated as follows: Under orders issued by the Police Department all prostitutes are obliged to register at the Municipal Clinic, and submit to a medical examination at stated intervals of five days.

Originally a segregated district was established, in which district houses of prostitution might be tolerated upon compliance with police regulations. This provision, however, is not strictly adhered to, the police commissioners allowing some houses outside the restricted district (strict segregation not having proved practicable, at least at present). The keepers of houses of prostitution are forbidden to harbor any inmate who does not possess a certificate from the Municipal Clinic showing that she had been found free from disease at her last examination. For the first offense of any infraction of this regulation the keeper of the house is called before the captain of the district and warned that a repetition will mean the closing of her house, a measure that has not proved necessary to date.*

Two police officers, specially conversant with and fitted for this character of work, are permanently detailed to the clinic and make daily visits to the various houses, checking up the inmates and seeing that the regulations are complied with.

Clandestine prostitutes who are arrested and brought before the police courts are sent by the police judges to the Municipal Clinic for examination pending the disposal of their cases, and on condition of having their sentence suspended are induced to present themselves for subsequent regular examinations.

*December 18 and 19 the first enforcement of this order was carried out, including two houses belonging to a single owner who had violated this rule.

Low dance halls and similar resorts with female attractions are regularly looked over now, and we expect within a short time to enroll the women contingent of these places on a special list of our clinic and oblige them to carry regular books.

The clinic is operated by a citizens' committee, known as the advisory committee, consisting of Dr. Julius Rosenstirn, chairman; Dr. Martin Regensburger, president State Board of Health; Mr. Ford and Mr. Morrison, two business men; Mr. Roncovieri, superintendent of public schools, Father Wymen, a member of the Paulist Order, and Mr. W. H. Metson, Park Commissioner.

The staff of the clinic consists of a superintendent and two female clerks, a chief clinician, an assistant clinician, a female physician for the

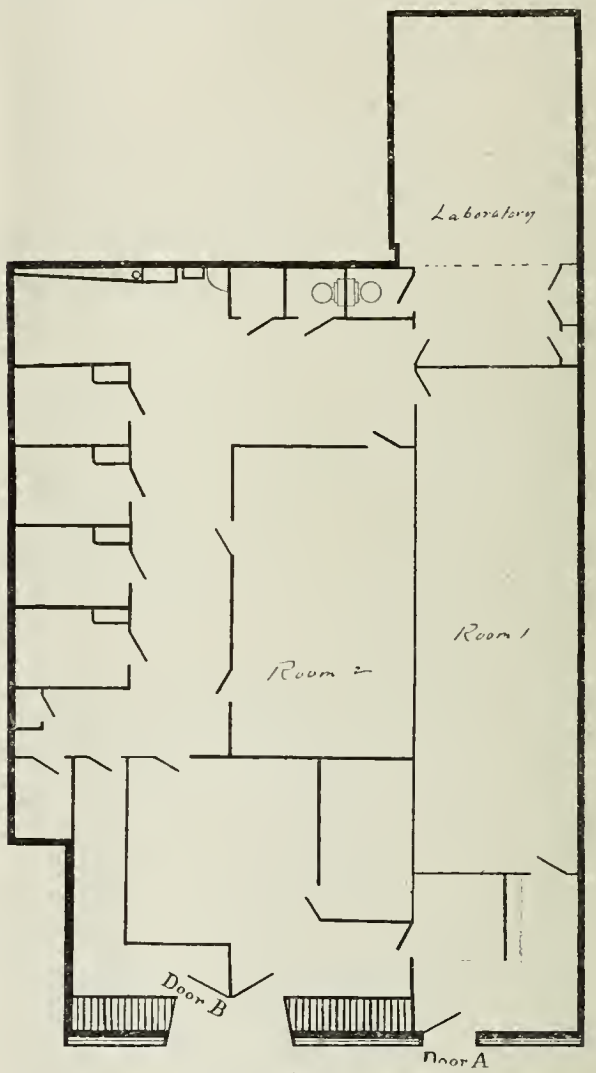

Fig. 1.—Floor plan of the clinic.

morning treatment hours, a bacteriologist (who is also a graduate physician), a trained nurse, a matron, and a janitor.

Every safeguard has been adopted against the possible practice of collusion in the examinations.

The attached sketch (Fig. 1) of the floor plan of the clinic will help explain the method used in examining patients. All women enter at door *A*, where they are registered on Form I (Fig. 2), and instructed to bring two photographs on their next visit. One of these photographs is then attached, as marked. The examination card (Fig. 3) is given to her, bearing her number. The coupon attached is torn off, and sent by carrying basket

to the matron. The patient enters waiting room No. 1 and awaits her turn for examination. The matron calls the patients by their numbers, consequently the examining physician does not know the name of the patient nor the house she comes from —he knows her only by a number. She is placed in one of the examining booths and the clinical examination is made. If clinical symptoms of lues are found, a Wassermann is added to the examination. For gonorrhea, smears are taken from any suspicious part, as urethra, Skeen's glands, vagina, Bartholinian glands, and cervix, are deposited in the correspondingly marked divisions of the slide-carrier, and sent to the laboratory for examination whilst the patient goes into waiting room No. 2 to await her report. After the laboratory examination has been concluded, the report is sent by carrier-basket to the clerk in the record office, and if satisfactory, the patient is furnished with a small pocket case (Fig. 2) which contains a duplicate of her record, and a card showing the date of her examination and that the same was satisfactory. This card is signed by the clerk whose signature is the one recognized by the police. The record is firmly fixed in the book by means of an eyelet, and cannot be

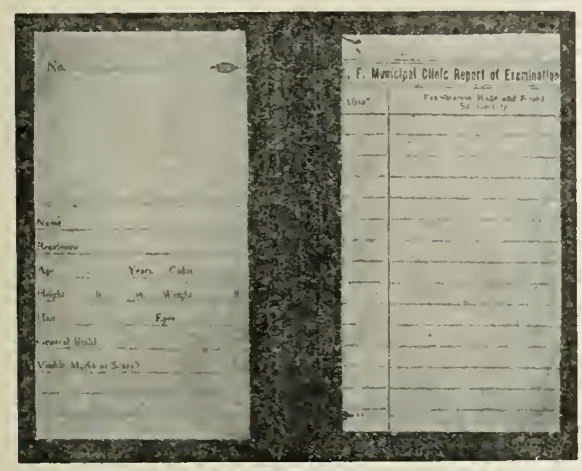

Fig. 2.—Patient's certificate.

removed without destroying the case. The patient then leaves by the exit door (door B).

In the office, the "*Master Card*" (Fig. 3), with one photo attached, is filed numerically, controlled by index cards, white for whites, and blue for other races. There is also a record kept of the inmates by houses, and the names are filed both by the first and surnames. A control card is made out (Fig. 5) which is filed under the four cardinal points of height, weight, color of eyes, and color of hair, thus providing a further identification in case of change of name. After her first registration, a woman receives on subsequent examinations, one of the cards (Fig. 4) marked when to report again. Upon her next visit, she surrenders her book at the cashier's desk, and it is returned to her after the same procedure as upon her first examination, if found satisfactory.

In case she is found diseased, a blue treatment card is issued to the patient, the stub being retained by the nurse.

The female physician is in attendance every morning between the hours of nine and eleven, for the treatment of the regular cases.

In case a woman refuses to submit to treatment, and continues to ply her trade, she is arrested, charged with vagrancy, ordered to the hospital for treatment, and detained there until cured.

The examinations are made in the afternoon from one to five.

Each person registered is supposed to report every five days. In case of illness or menstrual trouble, she must notify the clinic by telephone of the cause of her failure to keep her appointment.

A fee of fifty (50) cents is charged for each examination. No other charge is made and no gratuity of any kind can be accepted by any attaché of the clinic. (Large notice cards notifying the women of this rule are posted throughout the clinic, and on the door of each booth.)

All treatment furnished by the clinic are free to the patient. In cases that require hospital care, or where financial difficulties of any kind make it desirable, or in obstreperous cases, hospital attention is provided and paid for by the clinic. She is only charged for her regular examination.

The clinic is entirely supported by means of this fee. The funds are under the control of the advisory committee and are audited by a regular public accountant every month. A surplus fund is accumulating and is being saved with a view of establishing later an interim home for rescued girls of this class.

After an infected girl has been declared cured by her physician, she must report on three successive days to the clinic, when a smear is taken each time, and if advisable a tentative nitrate of silver injection added, and examined. For syphilis, a Wassermann is made, together with a thorough examination. Should the examination prove negative, she is furnished a card (Fig. 6) for free examination which must be made by the chief clinician, and if everything is all right her book is returned to her.

The laboratory of this institution is fully equipped and Wassermann tests are made in all suspicious cases and in every new registration.

This card (Fig. 7), samples of which I take pleasure in passing around, is enclosed in every book, and particular attention is paid in helping the women to understand it.

Inside the door of every private room of the houses of prostitution this card is posted:

ASK FOR THE
MUNICIPAL CLINIC BOOKS
AND SEE THAT THE LAST EXAMINATION
HAS TAKEN PLACE WITHIN FIVE
DAYS, PRECEDING TO-DAY.

. . . The public should realize, however, that notwithstanding the great improvement of conditions through these regular examinations, no guarantee of absolute safety can be assured.

MUNICIPAL CLINIC,
682 Commercial Street.

In every booth and all waiting rooms cards reading as follows are shown:

THE FEE PAID FOR EXAMINATION IS THE ONLY FEE THAT WILL BE ACCEPTED BY THIS INSTITUTION. ANY CASES COMING FOR TREATMENT RECEIVE ATTENTION ABSOLUTELY FREE OF CHARGE.

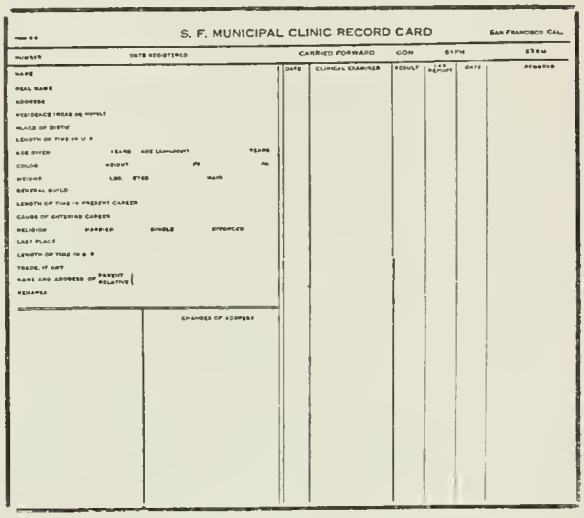
NO GRATUITY OF ANY KIND CAN BE ACCEPTED BY ANY NURSE, PHYSICIAN OR ATTENDANT UNDER ANY CIRCUMSTANCES WHATSOEVER.

ANY VIOLATION OF THIS RULE WILL BE PUNISHED BY THE DISCHARGE OF THE EMPLOYEE ACCEPTING THE GRATUITY, AND THE PENALIZING OF THE PERSON GIVING THE GRATUITY BY WITHHOLDING HER CERTIFICATE.

In the waiting room No. 2, where the women

await their reports, the following notices are displayed:

PATIENTS SENT TO THE CITY AND COUNTY HOSPITAL FOR TREATMENT ARE PAID FOR BY THE CLINIC, TREATED IN A SPECIAL WARD, AND ARE NOT SUBJECT TO STUDENT EXPERIMENTATION.



S. F. MUNICIPAL CLINIC RECORD CARD

and above a properly locked box, of which the Chairman of the Advisory Committee only has the key:

DEPOSIT COMPLAINTS HERE. THIS BOX WILL BE OPENED BY THE ADVISORY COMMITTEE ONLY. ANY COMPLAINTS ATTENDED TO PROMPTLY.

This now is in brief outline a sketch of the history and method of our 18 months' old work of a sane and humane sanitary reglementation. What is the attitude toward it now of our people, laity and professional, and what are the arguments brought forward against regulation?

Talcot Williams declared, "The laity of America would never either register prostitution or insist on compulsory examination, neither would it segregate the prostitutes." Is it really the American laity who opposes so strenuously, so unalterably, a sanitary protective measure? The laity who, upon the dangers of contagious diseases made known by the medical profession, submit, in cases of measles, scarlet fever, diphtheria, smallpox, etc., willingly to quarantine isolation, or forcible removal to a contagious disease hospital? The people approve even a life-long isolation or incarceration for leprosy, a disease known to be so very difficult to transmit by contagion that this fact now established through some isolated cases has long been doubted.

Would they object so strenuously if they knew the dangers, the terrible ravages due to venereal diseases; the fact that 80 per cent. of deaths from inflammatory diseases peculiar to women, 75 per cent. of all gynecological operations, and more than 60 per cent. of all gynecological work is due to infection? That up to a few years ago, before the Credé prophylactic eye-treatment was generalized in Germany, and up to now where it has not been adopted, 80 per cent. of disastrous inflammation of the eyes (ophthalmia) and 20 to 25 per cent. of all blindness has been caused by gonorrheal infection chiefly due to the passing of the newborn babe through the diseased maternal genitals? Is it not enough that about 80 per cent. of syphilis-infected children die in their mothers' wombs, and the 20 per cent. living carry with them the life-long marks and defects of mind and body as their heirloom, transmissible again to their offspring? Or would they also consider as a negligible quantity the effect of acquired syphilis, its destructive work on the vital organs, its causation of paralysis, locomotor ataxia, insanity, with the unceasing suspense of the Damocles's sword during the victim's lifetime? Perhaps the American laity might also regard the enormously great annual number of victims to infection with venereal diseases, but a trifling matter.

The Prussian Government in the year 1910 felt curious enough to send inquiry sheets regarding the number of such cases treated during the preceding year to each and every physician within its dominion. A conservative estimate based on the answers received gave the astounding result of 500,000 cases for the Kingdom in a year. Even if we allow for our country conditions ever so favorable as compared with Prussia in this particular respect, and simply grant for America's unhampered dissemination of venereal diseases no greater numerical infection than Prussia shows with its strict regulation, we would have in our own country the amazing sum of 1,500,000 venereally infected cases annually. Do you believe that if this were generally known the public at large would not eagerly adopt any and all means that promise even a slight degree of betterment?

But instead of publishing these appalling facts broadcast, the public press and periodicals shun the merest mention, still more the discussion of the sex problem and its dangers, the greatest perhaps, at the present time, which threaten the health and strength of our nation. In place of such shocking reading matter, many of their columns reek with the chaste advertisements of thinly veiled solicitations of prostitution from so-called masseuses and the freely offered help of abortionists to hasten retarded or irregular menstruation.

This prudery of the press, stimulated through the fear of excommunication by the purists, the moralists, and the pharisees, extends even to scientific publications. In a recently published work of sixteen enormous volumes an American encyclopedia in the style of the Encyclopedia Britannica, one looks in vain for such words as "prostitution," "prostitute," "nymphomania," etc., even the word "sex" has been carefully omitted.

Private endeavor has come to the rescue, and all honor to the courageous men who first founded the American Society of Social and Moral Prophylaxis of New York, the Society which took the initiative

in popularizing the knowledge of normal and pathological conditions arising from sexual intercourse. Similar associations were formed in other cities and finally a national Association, the American Federation of Sex Hygiene, was formed for the education of the public in the physiology and hygiene of sex.

In falling heir to this task, the Federation did not limit its work to the spreading of the new gospel of Sex Hygiene, but passed resolutions which, by virtue of the Society's adoption, were raised to and heralded as dogmas and held unassailable.

Following the examples of the International Con-

gress in Brussels, and the German one for the Prevention of Venereal Diseases, the Federation for Sex Hygiene pronounced as the first dogma, that sexual intercourse is unnecessary to health, or in other words, that absolute sexual continence is not injurious. It is unnecessary to call your attention to the fact that the foremost neurologists to-day contest the truth of this pronunciamento very sharply, so this infallible dogma, like its relatives of the ecclesiastical councils, is subject to correction.

Another dogma, pronounced later but with equal assurance, is that all attempts at reglementation must be abandoned; they are useless, nay, even injurious to any endeavor to prevent the spread of venereal diseases. Its full and permanent adoption throughout would abolish a sanitary regulation of prostitution, this main source of infection of venereal diseases. Even if such a high-minded association declares itself for a dogma of that sort should that throttle alike regulatory progress and prevent the discussion of this momentous question forever? I do not think so, and will try to review briefly the points of opposition to reglementation.

It is asserted that hitherto, inspection has been imperfect in the registered houses of prostitution, and that it does not reach secret prostitution at all. Let us grant that for argument's sake. But see what this imperfect inspection accomplishes.

I show you here a tabulated report of our activity during the 18 months of our clinic's existence. You see the reduction of morbidity from 146.8 per 1,000 to a fairly steady rate of about 50 per 1,000. The one month of May requires an explanation. During the month of June, the American Medical Association convened in Los Angeles, and the President of our last Board of Health, read a paper there before that Association, treating of the work of the then 3-months-old clinic, for which the figures of these first three months were used. In his endeavor to present a most favorable impression, his influence as president of the Board of Health, and the then managing spirit of the clinic, was perhaps unconsciously exercised to keep the percentage of diseased cases as low as—well, as you see it here—whilst when normal conditions were reestablished, the percentage reassumed its normal proportions:

The houses containing by far the largest contingent of prostitutes everywhere are the cheap houses; with us the "One Dollar Houses." The daily expenses of an inmate of such a house are at least $10 per day; $3.50 to the keeper of the house, $2.50 for food, rent for her private sleeping place from one dollar and a half up; the rest, for the clothes, washing, and incidentals, not counting the contribution for the protection and to the support of the cadet. In order to keep even she has to accommodate 12 to 15 visitors a day, a number ordinarily considerably exceeded. Let us say that only fifty per cent. of about one thousand active registered prostitutes occupy these cheap houses. Our figures show a reduction to nearly one-third of the original morbidity during the short period of our existence. Deduct from that a sufficient allowance for possible sources of error; we still have fifty per cent. and to spare. Among those five hundred, seventy-five diseased women would have been plying this trade except for the action of our clinic. Regulation eliminated at least thirty-seven. Thirty-seven times ten makes three hundred and seventy men a day, or one hundred and thirty-five thousand and fifty cases a year who escape the risk of infection, not including all those who were equally fortunate in the high priced houses by reason of the control we exercise.

Is that not a number large enough to stimulate our efforts to overcome any obstacle and all prejudices in order to help the parties concerned? As to secret prostitution, I have outlined to you what we are doing to have that element submit to regular ex-

aminations, and we feel certain of getting in time, a very large proportion. If they once realize, as we have demonstrated to the satisfaction of their registered companions in misery, that no graft is practised or permitted, and that this Institution acts in a friendly sense and manner for their benefit by reg-

ular sanitary inspection, that contingent will flock voluntarily to the clinic. Their confidence has to be gained by gradual and difficult education, and no unwarranted harassing practised or permitted.

"Oh!" cry out the Abolitionists, Purists, and Moralists, "You are condoning a crime." Are we, really? Have the views upon sexual relations not undergone any change from the medieval ecclesiastical condemnation of many centuries ago?*

While from an ethical standpoint, prostitution constitutes one of the most revolting degredations of the human frame and mind, the passing of money in an otherwise inoffensive action should not stamp it legally as a crime. Who knows better than you, my dear co-workers, that the grinding machinery of our social structure is responsible for the continuous supply in this nefarious trade? A lenient protective treatment of those unfortunates, who are compelled, or think they are compelled, to sell their bodies, corresponds to the charitably understanding spirit of our scientific age, in contrast with the harshly unbending one of fanatic orthodoxy.

The regulation we aim at gives also a protection against extortion. An obedience to the sanitary measures and to the laws of ordinary circumspection, gives freedom from authoritative harassment. As protection against this nightmare of their existence is no longer essential, the cadet loses a large share of his importance and influence, and a less odious relation between the prostitute and her friend may be hoped for.

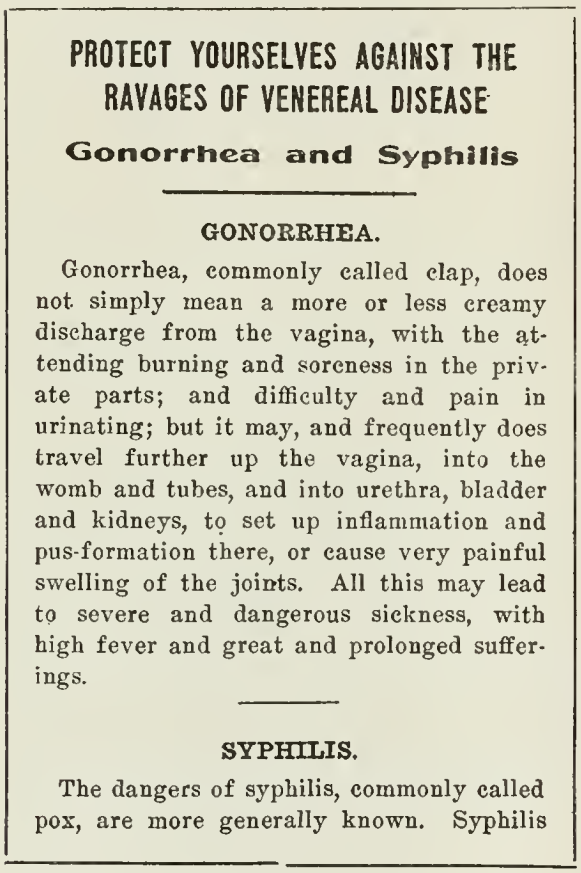
*In spite of the unjustifiable survival of antiquated dead-letter laws, public opinion in the present age does not condemn sexual intercourse among single persons unqualifiedly as a crime or vice. Regardless of the Criminal Code, society recognizes the elementary passion of sexual desire as a natural endowment of the normal red-blooded male individual and its reasonable satisfaction a more or less personal matter.

It has been argued that sufficiently frequent examinations of prostitutes charge the community enforcing them with an exceedingly heavy expense, inordinately so, relative to the good it accomplishes. Whilst we do not recognize that any reasonable amount of money spent for improving the health of a community is wasted, we have demonstrated beyond a reasonable doubt that this work can be done effectively for a comparatively small amount, and further, that the total expense can and should be borne by the main beneficiaries who pay it willingly for control against infection, and insurance for a paid-for-right to absolutely free private medical treatment.

Our success with the treatment of gonorrhea has been very gratifying. Before January, 1912, financial difficulties made it necessary to entrust our graduate nurse with carrying out the ambulatory treatment of the infected patients of the clinic under the supervision of the head clinician. Since the first of the year we have employed an excellently fitted female physician for this department of our work, and the percentage of the total number of detained infected cases applying for treatment of the clinic has gratifyingly increased:

| Month | Number of Diseased Cases | Number Treated in Clinic | Per Cent. |
|---|---|---|---|
| 1912 | | | |
| January | 43 | 25 | 56.1 |
| February | 23 | 13 | 56.5 |
| March | 38 | 26 | 68.4 |
| April | 48 | 30 | 62.5 |
| May | 54 | 29 | 53.7 |
| June | 29 | 25 | 86.2 |
| July | 40 | 33 | 82.5 |

Of these 181 cases treated by Dr. Campbell, at the clinic, 129 have been discharged and cured; 42 cases left without completing their course of treatment



PROTECT YOURSELVES AGAINST THE RAVAGES OF VENEREAL DISEASE

Gonorrhea and Syphilis

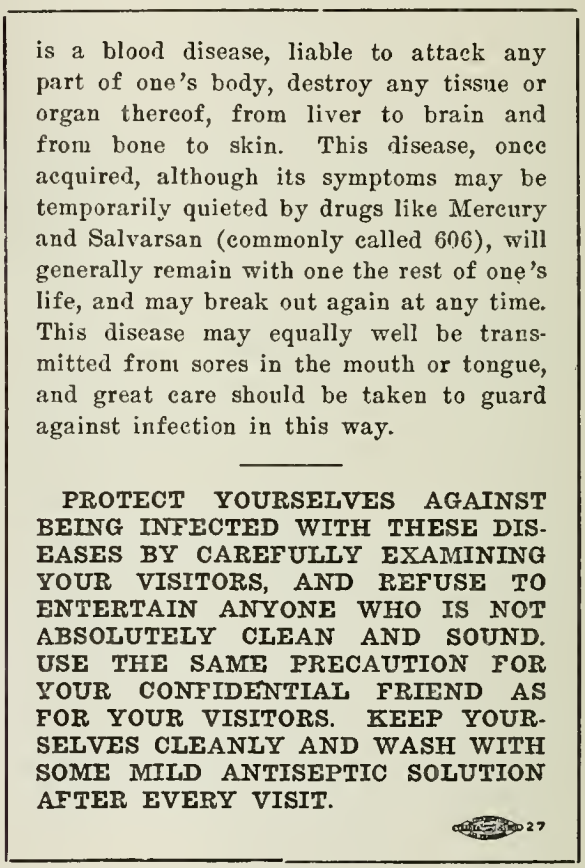
GONORRHEA.

Gonorrhea, commonly called clap, does not simply mean a more or less creamy discharge from the vagina, with the attending burning and soreness in the private parts; and difficulty and pain in urinating; but it may, and frequently does travel further up the vagina, into the womb and tubes, and into urethra, bladder and kidneys, to set up inflammation and pus-formation there, or cause very painful swelling of the joints. All this may lead to severe and dangerous sickness, with high fever and great and prolonged sufferings.

SYPHILIS.

The dangers of syphilis, commonly called pox, are more generally known. Syphilis

Page 1.



is a blood disease, liable to attack any part of one's body, destroy any tissue or organ thereof, from liver to brain and from bone to skin. This disease, once acquired, although its symptoms may be temporarily quieted by drugs like Mercury and Salvarsan (commonly called 606), will generally remain with one the rest of one's life, and may break out again at any time. This disease may equally well be transmitted from sores in the mouth or tongue, and great care should be taken to guard against infection in this way.

PROTECT YOURSELVES AGAINST BEING INFECTED WITH THESE DISEASES BY CAREFULLY EXAMINING YOUR VISITORS, AND REFUSE TO ENTERTAIN ANYONE WHO IS NOT ABSOLUTELY CLEAN AND SOUND. USE THE SAME PRECAUTION FOR YOUR CONFIDENTIAL FRIEND AS FOR YOUR VISITORS. KEEP YOURSELVES CLEANLY AND WASH WITH SOME MILD ANTISEPTIC SOLUTION AFTER EVERY VISIT.

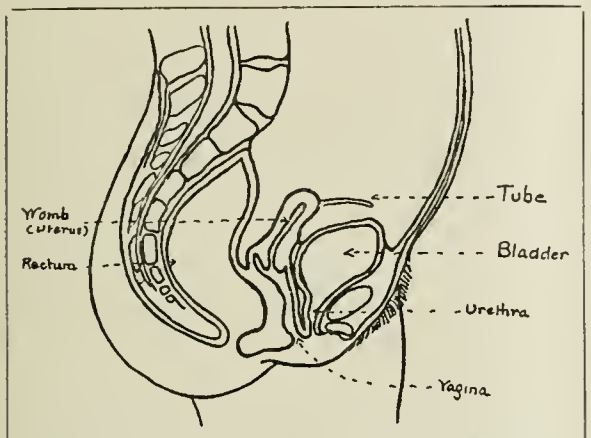
27

Page 2.

and disappeared. Of the 129 cases mentioned above, dismissed as cured, only six have had recurrences, 3 of whom had refused to have the Bartholinian glands slit open for treatment.

In addition to the above cases, six cases of syphilis were treated under our auspices at the hospital, and after injections of salvarsan, and the disappearances of clinical evidences of disease under this and subsequent treatment had their books returned to them subject to observation and control.

The gonorrhea cases have to undergo three successive examinations, followed where advisable, by a tentative nitrate of silver injection. Only if all three and the nitrate of silver injection show the absence of acute or chronic inflammatory clinical symptoms and of the Neisser's organisms, the patient has her book returned to her, and is thereby entitled to take up her trade again. We therefore cannot agree with those who claim gonorrhea incurable and give this reason for an alleged inefficiency of sanitary regulation. Our results have proven



Look at and study this lengthwise halfcut (Longitudinal section), through female pelvis with its organs, and try to understand it.

**ASK THE DOCTOR AT THE CLINIC HOW TO MAKE PROPER EXAMINATION OF YOUR VISITORS, AND ABOUT ANYTHING ELSE YOU DO NOT UNDERSTAND; HE WILL GLADLY EXPLAIN.**

**DO NOT FORGET THAT THE MUNICIPAL CLINIC IS YOUR FRIEND AND FOR YOUR OWN PROTECTION.**

Page 3.

FIG. 7.—Card enclosed in each patient's certificate. (The first 2 pages are shown on p. 472.)

the fallacy of this. A cure from syphilis can never be absolutely claimed, but in practically all cases a rational treatment insures at least a temporary innocuousness to others, which should be watched by regular examinations.

Let us look over the statistics made by honest, painstaking and impartial investigators regarding the effect of regulation upon public health. Statistics of such a nature must fulfil peculiar conditions to be of any value. During the term of observation the material must be practically unvarying as to age, physical strength, and conditions of life and living. The medical control must be constant and accurate, and similar standards must prevail where comparisons shall be deemed valid. The armies of the various nations are the only large bodies of men that fulfil to a nearly ideal degree all these claims, and with army reports we shall occupy ourselves chiefly.

In 1871 the British Royal Commission and in 1879 a select committee were appointed to investigate the effect of the Contagious Diseases Prevention Act. This was, as you all know, an act providing for the compulsory medical examination of prostitutes, and by detention in the hospital of those found diseased in garrison towns. The direct evidence collected by these two official bodies was strongly in its favor, alike with the diminution of disease among the troops in the protected towns, the absence of complaints, and the good effects on public order to which even clergymen and other residents testified. The majority of the committee reported accordingly after a three years' inquiry. Agitation against the act by purists and moralists became very violent, however, and in 1883 the House of Commons with the usual understanding of legislative bodies for medical affairs, passed resolutions condemning compulsory examination by a vote of 182 to 110.

In order to let you see the character of some of the evidence gathered by these committees of skilled observers I will show you their comparative table demonstrating the decline in cases of venereal diseases in towns protected by the Diseases Act and in unprotected towns. Primary sores, secondary syphilis, and gonorrhea are considered separately:

INFLUENCE OF BRITISH DISEASES ACT ON ARMY HEALTH

| Period | PERCENTAGE OF DECLINE FOR: | | | | | |
|---|---|---|---|---|---|---|
| | PRIMARY SORES | | SECOND. SYPHILIS | | GONORRHEA | |
| | Not Subject | Subject | Not Subject | Subject | Not Subject | Subject |
| 1861–72..... | 9 | 40 | 5 | 34 | 3 | 8 |
| 1860–73..... | 26 | 60 | 10 | 49 | 18 | 24 |

That even a not very humanely conducted control by police administration is effective, in spite of the often expressed doubts, is shown by the gradually lessened number of attempted escapes from control and the number recovered by the police in Paris as reported before the Brussels Congress.

Only the first and last years are given here:

REPORT OF 1900 INTERNATIONAL CONGRESS OF BRUSSELS

| Year | Registered | Disappeared | Rest. to Control |
|---|---|---|---|
| 1888..... | 4591 | 1779 | 1491 |
| 1889..... | 4591 | 2125 | 1309 |
| 1896..... | 5900 | 1190 | 615 |
| 1898..... | 6018 | 344 | 498 |

Parent-Duchâtelet, Behrend, Hugel, and many other American and European authors and nearly all other writers prior to 1850 never doubted that the immense sanitary advantages from that kind of regulation were easily demonstrable.

The eminent Russian physician Stürmer is authority for the statement that in Russian cities when control is released, venereal diseases increase and the reverse when control is taken up again. In the City of Dorpat, known as an example for the severe character of its local venereal diseases, the commander of the garrison reported in 1898 that after three years of effective regulation not one out of 1,000 men stationed there had contracted syphilis during the year.

Statistics from Norway, especially from Christiania, indicate the same relations between control and prevention of diseases. The Italian army statistics show undoubted increase of the spread of venereal infections after the abolition of regulation. You may judge for yourselves a comparative statistical table of the morbidity from venereal diseases in

some of the various European armies during the twenty years from 1876 to 1895 inclusive. The arrangement of the countries begins with the one where regulation is strictest and passes gradually to the one where it has been abolished.

ADMISSION TO HOSPITAL FOR VENEREAL DISEASES PER 1000 IN EUROPEAN ARMIES

| Year | German | French | Austrian | British (Home) | British (India) |
|---|---|---|---|---|---|
| 1876..... | 28.8 | 57.0 | 65.8 | 146.5 | 203.5 |

| 1895..... | .... | .... | .... | 173.8 | 522.3 |

I have been informed that until lately our own army and navy showed the same conditions as the English.

In the light of these investigations into the usefulness of sanitary control we feel that regardless of the outcries of so-called purists and moralists further efforts with regulation are certainly justified.

The attitude of the American public is not as forbidding as these people would make us believe. Cities like Chicago, Cincinnati, and Sacramento, whose representatives have inspected our work, made requests for samples of our forms and for information regarding our methods, with a view of introducing both.

We wrote to every city of over 25,000 inhabitants in the United States, asking for and receiving from 83 information as to the presence or absence of regulation in their municipalities, their means for the prevention of the spread of venereal diseases and as to the effect of either.

Thirty of these cities tolerate prostitution under all degrees of regulation from the merest apology to well organized systems—claiming generally satisfactory results. Fifty-three replies claim to prohibit prostitution absolutely—26 of them, mostly New England towns like Fall River, Worcester, Lowell, New Bedford, claim satisfactory results and total absence of prostitutes. All Massachusetts cities of this category assert with strange unanimity that their young men, if sexually inclined go to Boston to gratify their desires, whilst Boston in the report sent us, states its absolute prohibtion of prostitution. Nothing more convincing of the necessity of sanitary regulation could be given than the answers to these questions in their totality offer, and I sincerely regret that the lack of time does not allow me to read you this interesting documentary evidence.

The voices of those who come into close contact with these elements of our society of those who see their daily life and know intimately their associates, their practices, and their various ramifications extending into all parts of our social structure, speak loud enough for the benefits, for the desirability of regulation, but they are timid as yet, and are drowned by the vociferous outbursts of the purists.

Even such a highly intelligent and conscientious official as Police Commissioner O'Meara of Boston writes in his most interesting "Record of the Enforcement of the Law Against Sexual Immorality (Since December 1, 1909 to 1911)": "If a future Police Commissioner were intending to pursue the same course with respect to the business of vice that has been followed for four years, I should advise him that he might expect loyal support from the police when once he had convinced them that he was in earnest, little encouragement from courts, bitter hostility from persons whose profits were curtailed, indifference from the public, and from a few enthusiasts in the name of social purity, whose admirable purposes are not sustained by straight and intelligent thinking, he would be sure to receive some measure of abusive criticism."

A certain sort of sanitary regulation we must have. We need it for the protection of the coming generation, for the protection of our youth, of our Nation's manhood and womanhood, and especially for the protection of the unfortunate women, victims of social imperfections and cruel misfits, to correct which it may take centuries to come and we can not —dare not wait.

But just as much as we advocate regulation we want it a different kind from what it has been in the past, a new regulation unadulterated with persecution. No regulation, we believe, will ever gain the sanction of right-minded people or gain its end, unless it is first and principally based upon an absolutely helpful and fair dealing with the prostitutes themselves.

The second Brussels Conference passed as Resolution No. 2, "That prostitutes suffering from venereal maladies ought to be considered not as criminals, but as patients."

We go farther than that. We consider all the city's prostitutes as patients of our clinic to whom we extend the helping hand of the medical friend and advisor and last, but not least, of the educator. We educate them to the knowledge of the perils of their trade and the benefits derived from a controlling institution like the Municipal Clinic.

We gain their confidence by absolutely fair and dignified treatment, coupled with the convincing assurance that no graft of any kind is sheltered or condoned.

We raise their self-esteem by making them feel that the trifling examination fee charged (or remitted if financially distressed) for a temporary clean bill of health in a perilous trade, gives them a rightful claim to free medical treatment; should the misfortune of infection befall them. This free treatment entitles them to a paid-for hospital care if necessary or desirable, and exempts them from an objectionable and sometimes humiliating demonstration before student classes. And let me add right here, although we enforce no lock-hospital methods, but have our patients distributed in regular order of admissions throughout the wards, we register only one escape among all the hospital-confined cases.

We educate these women by impressing upon their generally undeveloped minds, the ever-present danger of infection with its disastrous consequences, and through the verbal instruction of our medical staff teach them as well as possible to examine their visitors and recognize the symptoms of venereal disease if present.

I have shown you the cards we place on the inside of each and all inmates' doors to their private rooms, for the notice and benefit of the patrons of these resorts. They call upon the visitor to inspect

the girl's book and convince himself of an official examination having been made within the preceding five days. These cards help us toward the regularity of our control, but at the same time, avoid the raising of a feeling of false security in the public mind by announcing that in spite of all these precautionary measures, no guarantee of safety can be assured.

The large and growing percentage of infected women that apply for treatment in our clinic, relieves us from the reproach that our system or regulation drives these unfortunates into other parts of the State or country where, unhindered by regulation, they might continue their trade.

We are free from all kinds of political influence. We were severed accidentally from the McCarthy Board of Health, which created our advisory committee. A judicial decision unseating several of the board's members, among them its president, an ex-officio member of our committee, who lost his membership through this decision. When our committee in March, 1912, approached Mayor Rolph's newly appointed Board of Health with the request to take over the Municipal Clinic with its fully paid-for equipment and its cash surplus in the bank in order to relieve the committee from its labors, we were refused. Not being willing to abandon a task which the men who were in it had recognized as most important and beneficial to the community at large, the committee continued its work alone, independent of the Board of Health, but with the gratifying protection and active support of the police authorities, executive and judicial. They have, after faithfully watching our endeavors learned to trust us, and I may say, simply stating a fact, that we enjoy at the present time the confidence alike of the legal authorities and the poor unfortunates whom we consider our wards.

The greater part of this encouraging result could only be gained by the tactful and efficient services of our entire staff, their assisting nurses, the police officers, the office force, and by the enthusiastic devotion of the clinic's superintendent. This spirit made it possible that although rescue work is not included in our programme, and no missionary work attempted, still in the short time of our existence 121 women were led into the decent paths of society, and cared for during the intermediate period until appropriate work could be provided for them. Forty of them have returned to their former life, the others have, to the best of our knowledge, not relapsed up to date.

In addition six neophytes were saved from entering a life of shame and five girls under the age of consent (18 years) were turned over to the care of the Juvenile Court.

Through the activity of our institution, our officers arrested twelve white slavers who were prosecuted—some in the Federal and some in the State courts—with the justifying result that in these most difficult cases, eight were convicted, only two acquitted, and two are still awaiting trial.

Appreciating the opportunities that our Institution furnishes for the discovery of this class of criminal cases, the municipal and especially the federal authorities continually ask our help and assist us in our efforts.

You easily see that our work does not oppose or hamper rescue work or educational efforts of the Society for Sex Hygiene type. On the contrary it materially helps every kind of work for the betterment or, if you will, the abolition of these sad conditions, and we are most willing and glad to assist in every possible way.

Fortunately for the work, our independence from politics permits us to fill positions for merit only, and it is perhaps this favorable administrative condition that caused the incumbent president of the Board of Health, a lawyer of high standing and reputation, to express to the author of this paper, as his opinion, "that the present independent state of the Municipal Clinic should be preserved so that persistent and sometimes irresistible political demands for appointments might be ignored."

If I may formulate certain requirements for the success of modern institutes for the sanitary regulation of prostitution, the following would be fundamental:

1. Prostitution, if regularly and officially supervised, although morally and socially abhorred, should not be punishable criminally, its regulation should be left to municipalities or counties.

2. The display of a spirit of helpful dignified sympathy by the institutional officers and employees for the unfortunates who come under their administration.

3. A persistent effort to educate the clients of the institution to the perils of their trade, to the methods of their avoidance, and to an appreciation of the Institute's beneficial services for their protection.

4. The inculcation of self-dependence by charging a small examination fee, sufficient to maintain the expenses of the institution and thereby insuring free and private medical, ambulatory, and unlock hospital treatment. This could be so arranged as to have the landladies assume part or all of the charges.

5. A police detail attached to the institution for surveillance and rounding up of delinquents by specially fitted officers.

6. Control of examination to be helped by cards similar to ours affixed in the private rooms of houses of prostitution calling for inspection of certificates of examination by the visitors, but disabusing their minds as to a possible feeling of safety.

I firmly believe if institutions for the sanitary regulation of prostitution were established and carried on along these lines throughout our country, the number of infections with venereal diseases would be very materially lessened, the injuries as well as the opprobrium resulting from the existence of prostitution greatly diminished, and a class of human beings benefited for whose debasement and degradation our vaunted civilization must be proclaimed chiefly responsible.

## TUBERCULOSIS IN EARLY LIFE.*

By EDGAR P. COPELAND, M.D.,
WASHINGTON, D. C.
ASSOCIATE IN PEDIATRICS, MEDICAL DEPARTMENT, GEORGE WASHINGTON UNIVERSITY.

During my brief connection with this society I have listened with much interest to papers and discussions upon the subject of tuberculosis. They have, however, so universally dealt with the tuberculosis of adults, and more particularly phthisis, that I am stimulated to present briefly a few remarks upon the disease in early life.

We observe, perhaps, no malady so strikingly influenced in its pathology and dependent symptomatology by age as is this one. Not only is the disease more prevalent in early life, and it is very much more prevalent than is generally believed, but it is attended with a much higher mortality. With the greater opportunity for infection, the morbidity is readily explained, the mortality is undoubtedly dependent upon the more insidious onset and the widespread character of the lesions.

While a small percentage of cases in the young have been definitely proven to be of bovine type, pointing to an infected milk as the source of their disease,[1] a more careful examination will, in the vast majority of cases, trace infection directly to another case or contaminated home. The pernicious habit of taking children to visit relatives ill with tuberculosis, and the unfortunate instances where children are dependent upon tuberculous parents for such care as they receive, are too numerous in our experience. Among the negroes, whose greater predisposition, for whatever reason, is an established fact, the vicious practice of putting out the young with nurses while the mother is at work for the day is common. These women care for the children of a number of families for whatever money consideration, necessarily small, they can receive, and it may be safely assumed that, did their physical fitness permit, they would themselves be at work for wage. In too many instances their physical unsoundness is tuberculosis in some communicable form. These children, many of them at the crawling age, are under such circumstances subjected, first to improper or insufficient food (especially is this true of nurslings deprived of breast milk), and secondly, to direct contagion from the tuberculous patient, from infected food, and finally from the infected house.

*Read before the Society for the Prevention of Tuberculosis, Washington, D. C., March 5, 1912.

That the offspring of tuberculous parents may be born with the infection cannot be denied. Indeed, according to good authority,[2] a more careful examination of such offspring reveals tubercle in a larger proportion than was formerly supposed. Nevertheless, such tuberculosis is relatively uncommon, and by that I mean the presence of lesions post mortem, under three months of age, and it is my firm conviction that the infant would be comparatively safe could it be given a proper environment. Eminent authorities scout the idea of intrauterine infection, and point to contact with the mother or nurse as the source of danger.[3] The rôle of environment is nowhere more strikingly shown than in the statistics of two foundling asylums, the one in Prague, the other in St. Petersburg. In the former, under the direction of Epstein, it has been the custom to remove the babies of the tuberculous from the sphere of contagion immediately after birth; in the latter, under Froebelius, no effort at separation is made. The differences in the results obtained present an irrefutable argument.

It might not be amiss at this point to say just a word about so-called scrofula. It is by no means unanimously conceded that conditions, such as this designation is generally recognized to cover, cannot exist in the absence of definite infection with the tubercle bacilli. By such authorities as draw a distinction scrofula is explained to be a condition resulting from an intrauterine intoxication, but without definite bacillary invasion. Such subjects are presumed to present structures such as diseased lymphatic tissues, etc., that make them susceptible in a greater degree to infection.

I believe all are agreed that, once infected, the mortality is very high. In fact, I should say that recovery after the manifestation of clear clinical evidence is exceptional. Nor does this mortality seem to be much influenced by the measures that have given such gratifying results in the treatment of the disease in adults. Kelynack has fittingly designated tuberculosis as "the great scourge of child life."

It is not within the scope of this paper to attempt to draw conclusions from the extensive and conflicting literature on the portal of entry of infection. Dr. Guthrie characterizes such an effort a fallacious proceeding. It seems much more reasonable to grant that any portion of the respiratory or gastro-intestinal tract may serve as a point of entry. If the involvement of the lymph glands at or near to this portal of entry may be accepted as evidence, we must concede the mucous membranes of the upper respiratory and digestive tracts to be most often penetrated. The consideration of this question is here of importance only as it helps us determine the source of infection and thereon base a proper prophylaxis. Infection present in milk, and I refer to bovine type of infection, might readily infect the mediastinal glands by effecting an entrance in the lymphoid tissue of the upper air passages or through the mucous membranes of the upper digestive tract. On the other hand, infection from a human source might be ingested and find the point of lowest resistance in the intestinal tract. Of much more importance, to my mind, is the work recently done by Park and Krumweide, showing the relative frequency of human and bovine tuberculosis in humans.[1] Their work gives the bovine organism as the cause of the disease in from 6 2/3 to 10 per cent. of cases occurring under three years

of age. Taking all things into consideration, it would seem, therefore, that the danger from the milk of infected cattle subordinates itself to the menace from environment.

In the tuberculous manifestations of early life the lymphoid structures bear the brunt of the attack. This predilection for the glandular structures is due to the greater activity of these tissues, the relatively greater size of the lymph channels, and the keen energy of the lymph streams, resulting from the more active metabolism of infancy. The bronchial or mediastinal lymph nodes are involved in an overwhelming majority of instances.* Owing to the tendency to latency, many cases of this nature escape recognition. Of one thing I am convinced, and that is that, could the problems of a greater number of the socalled atrophic infants be solved, the general conception of the morbidity and mortality in tuberculosis would need considerable revision. The newborn, like the laboratory animal, is most susceptible to tuberculous toxemia, and undoubtedly many serious progressive disorders of nutrition are the result of bronchial gland involvement.

The picture drawn by Soltmann[3] is one with which we are all familiar. "The innutrition, the sudden arrest of development, and the subsequent decline of body weight, with rejection of food and apathy; the disappearance of the fatty tissue, the sallow, wrinkled gray skin which has lost its natural turgescence and is covered with flaky desquamation and frequently with intertrigo, furunculosis, and multiple abscesses; the thin, hard strands of muscle standing out like folds, the legs adducted at the knee, edema of the angle and the dorsum of the foot; the unmotived dyspeptic symptoms; the mummylike, shrunken little face, the bones of the skull which overlap in the form of terraces; and the hollowed fontanelles, the sunken eyes, the wide-drawn mouth surrounded by radiating lines—such is the picture of these poor little unfortunates, who, without cough and without expectoration, but with a small, frequent pulse and atypical changes in the temperature, which is often subnormal, are certain candidates for death." Such a train of symptoms is not often diagnosed tuberculosis. Only when the general dissemination results, with its terminal meningitis, or pulmonary involvement, or peritonitis, is the etiology perfectly clear.

Not only do we have tuberculosis of the bronchial glands in infancy, but we find it dominating childhood up to the age of puberty. Most often there is early caseation and dissemination, but not infrequently a quiescence from encapsulation that only awaits the glandular activity of some infection, as whooping cough, measles, or influenza, for its quickening. Thus, I believe, may we explain the frequency with which the clinical symptoms of tuberculosis follow upon the above mentioned diseases. The recognition of diseased mediastinal glands is attended with considerable difficulty, the younger the patient the greater the difficulty. With the very young it must be very largely conjecture, based upon constitutional symptoms and the presence of a positive tuberculin reaction. As the child grows larger the evidence becomes more dependable and we are able to make out the presence of enlarged lymph nodes by physical examination. Impairment of the note in the first and second interspaces close to the sternum, more especially on the right side, or in the interscapular region from the third to the fifth ribs, is strongly suggestive of mediastinal tuberculosis. Pollak[4] in a recent paper states that there are two signs that surpass all others in diagnostic importance. First, the characteristic cough; secondly, the expiratory "panting" or murmur. According to this authority, the extremely high pitch of this cough is pathognomonic. He further adds that all other symptoms of bronchial gland tuberculosis are unreliable. The diagnostic importance of the cough is emphasized by Still, who describes it as clanging and paroxysmal, partaking somewhat of the brassy quality of the cough produced in the adult by aortic aneurysm, and easily mistaken for whooping cough.[5]

To revert to tuberculin as an adjunct to diagnosis. Pollak, whom I have previously quoted, attaches the greatest importance to a positive or negative cutaneous reaction in children. My own experience with tuberculin as a diagnostic agent has been limited to the Wolf-Eisner method as modified by Calmette and now generally abandoned, and the cutaneous or von Pirquet method. So few of my own cases have been controlled post mortem or by a subsequent development of unmistakable lesion that I cannot draw any conclusions from them. The employment of the tuberculin subcutaneously for purposes of diagnosis in children is not a common practice among pediatrists.

When the tuberculous processes in early life for one reason or another become disseminated, we have our attention all too frequently drawn to and concentrated upon the disorder of an organ or system in which the disease has made special inroads, often forgetful of the fact that diffuse tuberculosis exists. Consider, for instance, tuberculous lesions in the lungs of children. We are not here dealing with localized disease such as is most often seen in the adult, but probably with the terminal stage of a general disease. In numbers of autopsies at the Children's Hospital on children dying with tuberculosis, I do not recall a single case in which diffuse lesions were not present. The reports from a series of autopsies on adults present a very different picture. The frequency with which localized tubercle is found in the adult is shown in the last report of Dr. Kinyon for the Tuberculosis Hospital in this city.

Time does not permit me to discuss the many manifestations of tuberculous dissemination. I have dealt particularly with the disease as affecting the bronchial lymph nodes, first because it is the result of the invasion in the vast majority of cases, and secondly because it is the form most likely to escape our notice, at least in the very young. The impression that I wish to leave is this: that any tuberculous lesion in early life, be it superficial adenitis, osteomyelitis, or what not, is a cause for the gravest alarm, since it is, in almost all instances, merely the local expression of a serious infection. The modern trend of surgery in the treatment of tubercle in bones and joints, the conservatism, and the treatment of the patient rather than the lesion, are merely a recognition of the character of the disease.

I have previously made reference to the frightful mortality of tuberculosis of early life, and I have very little to say upon treatment. In the light of our present knowledge, tuberculin as a therapeutic agent has failed to produce the results so eagerly anticipated. About a year and a half ago Dr.

*Freeman found nodes involved in 126 out of 158 cases; Holt in 108 out of 119, and Northrup in every one of 125 cases.

Nichols very kindly treated a series of fifteen cases of cervical tuberculous adenitis for me in my clinic at the Children's Hospital. We were not able to observe that the course or character of the disease was altered in any respect. Most authorities, with the possible exception of Maragliano and Spengler, are agreed that its use in childhood is not unattended with danger. In the absence of a specific and in a condition in which we are so largely dependent upon the recuperative powers of the patient for whatever measure of success is to be attained, we must turn to prophylaxis for our results. Very little may be expected after infection is received.

The problem of prophylaxis offers numerous and serious difficulties in the solution of which sentiment must first of all be educated and directed into its proper channels. One point may well be emphasized not only for the laity, but the profession as well, and that is a sober regard for the seriousness of whooping cough, measles, and influenza in their relation to tuberculosis. While I am heartily in favor of blocking off every possible avenue of danger in the campaign against this disease, and I have in mind more especially the great amount of work that has been done in protecting the public from the dangers of infected cattle, I cannot help thinking that in proportion to its importance too little attention has been given to the providing of suitable environment for the young, who otherwise are doomed to the malady.

The most effective fight against tuberculosis is to be waged where it is most prevalent and where the highest mortality is observed, namely, in early life, and it is in this period that experience teaches us that we must look to a more efficient prophylaxis for any considerable decrease in the terrible mortality.

## USE OF THE FETAL MEMBRANES IN SKIN GRAFTING.

By NICHOLAS SABELLA, M.D.,

NEW YORK.

I wish to show by this method that the material or organs that are generally thrown away after we have delivered the child can be utilized to the best advantage in skin grafting.

Before going into detail, I wish to give the histology of the material which I use for this purpose.

Histology of the Amnion.—This is a thin membrane of fetal origin, consisting of an epithelial coat, and a thin layer of mesenchymal connective tissue. Its epithelium, whose surface is directed toward the fetus, consists of cuboidal or flattened epithelial cells which are derived from the ectoderm; they are firmly united with one another by means of intercellular bridges. The connective tissue forms a thin transparent layer of embryonic tissue in which are many cells. From the inner surface of this layer delicate processes pass to the surface of the chorion, to which membrane the amnion is loosely attached.

Histology of the Chorion.—This tissue includes a membranous portion which is in relation with the amnion, and a villous portion which forms the forest of the placental villi already described as lying between the fetal membranes, on the one hand, and the material decidua on the other. That portion of the chorion which enters in the formation of the placenta is known as the chorion frondosum, in contradistinction to the remaining portion of the chorionic membrane, which is loosely attached to the decidua vera and is called the chorion leve.

The membranous portion of the chorion may be said to consist of two layers—an inner or fetal layer of embryonic connective tissue, which is continuous with the similar tissue of the amnion, and serves for the transmission of fetal blood vessels on their way from the umbilical cord to the placental villi, and an outer layer which consists of intermingled groups of large cells, collectively forming the trophoblast together with masses of canalized fibrin.

I have mentioned the chorion in this place not as an indication for grafting this membrane, but only to show that this layer serves as a sublayer for the transmission of the blood-vessels from the umbilical cord and how the amnion is intimately connected with the chorion, thus receiving its nutriment from these blood-vessels present in the chorion by exudation or transudation. The membrane would not serve as a means for grafting because of its fibrous nature.

I wish also to present the histology of the umbilical cord which I use for grafting. The umbilical cord transmits the two umbilical arteries, which are spirally wound about the umbilical vein. These vessels are embedded in a non-vascular, gelatinous connective tissue, known as the jelly of Wharton, which is rich in cells and ground substances. The fibers, as in all embryonic tissue, are poorly developed and form only a loose network of very delicate fibrils. The connective-tissue cells and fibers are frequently arranged in membranous bands which extend lengthwise of the cord and in transsections present a peculiar concentric arrangement; the delicate membranes alternating with broad tissue spaces, and often inclosing the blood-vessels or forming incomplete concentric lamellæ about the circumference of the cord. The surface of the cord is clothed with an ectodermal layer of flattened epithelium which occasionally forms several layers of cells.

The umbilical vessels, the veins as well as the arteries, are peculiar in that they possess unusually thick muscular walls. Their smooth muscle fibers are disposed both longitudinally and circularly. In transsection the endothelial lining of the vessels is seen to be thrown into prominent folds by the contraction of the thick muscular walls.

Remnants of the allantois and occasionally of the yolk-sac as well are found in the fetal end of the umbilical cord even at full term. These appear in the form of indistinct epithelial tubes or columns, whose cells often show evidences of degenerative changes.

The outermost of the fetal membranes is the chorion; this is covered with vascular villi, which dip into the decidua capsularis and basalis. Inside the chorion is the amnion, a closed sac, which surrounds the embryo and is attached to its ventral wall at the umbilicus. The amnion also forms a sheath for the umbilical cord by which the embryo

is attached to the inner surface of the chorion; it is filled with fluid, the amniotic fluid, in which the fetus floats. The umbilical cord contains not only the blood-vessels which pass between a specialized portion of the chorion, which forms the fetal part of the placenta and the embryo, but also the remains of the yolk-sac and the duct by which it is connected with the intestine of the embryo.

The Development of the Fetal Membranes.

Amnion.—As the embryo is differentiated the surface of the ovum beyond its margins, formed by the somatopleure, is gradually raised as a circular fold, which is looked upon as consisting of head, tail, and lateral portions. The various parts of the fold rise quickly and converge over the embryo, which at the same time passes toward the interior of the ovum. Finally the folds meet and fuse together at a point which is called the amnion navel. As soon as the folds fuse the inner parts separate from the outer and form a closed sac. The inner wall of the sac is formed by the epiblast, the outer by the mesoblast, and both are continuous with the same layers of the embryo. But soon the space between the two, the amniotic cavity, becomes filled with fluid, and this increases in amount until at the end of pregnancy it is present in very considerable quantity. The allantois is an outgrowth from the ventral portion of the posterior part or the primitive alimentary canal, and it consists of a hollow process of the hypoblast covered with mesoblast. In the human embryo it appears at a very early period, before the amnion folds have separated from the chorion, and it conveys the allantoic arteries from the embryo to the chorion, and the allantoic vein from the chorion to the embryo. At first the allantois is very short, but as the amnion distends and the embryo passes further and further into the interior of the enlarging ovum it is elongated into a cord which, together with the remains of the yolk-sac, is surrounded and ensheathed by the amnion; this cord is called the umbilical cord.

In the human subject that portion of the allantois which lies in the umbilical cord consists entirely of mesoblast vascular in character, for the hollow pouch of hypoblast ends near the umbilicus.

In man the umbilical cord consists of: (1) An outer covering of amnion. (2) A core of modified mesoblast derived from the mesoblast of the allantois and the wall of the yolk-sac. (3) Remains of the hypoblastic portion of the yolk-sac. (4) The allantoic arteries and veins.

In the early stages immediately after the separation of the amnion from the chorion the embryo and the amnion are attached to the chorion by the allantois, and they are situated in a space which is part of the original cœlomic space between the somatic and the splanchnic mesoblast. This space is continuous with the cœlum in the embryo at the umbilical orifice. In the later period it is entirely obliterated, for the amnion is distended until its outer surface fuses with the inner surface of the chorion; and at the same time the umbilical cord is differentiated as the distending amnion surrounds and presses together the allantoic stalk and the remains of the yolk-sac.

Since these organs of which I have already given the histology are a direct derivation of the skin of the embryo, they ought to have also all the functions of the skin in full development. Hence because of their derivation from the skin these organs serve as: (1) A protection; (2) heat regulation; (3) respiration; (4) absorption; (5) secretion and excretion. Hitherto these organs have been considered useless after they have performed their primary functions. It is my purpose to show that this is not so, but that they may be further utilized by us.

These organs are a portion of a living organism, and since these organs would go on living if kept intact for an indefinite time, they should also continue to live if properly placed on a surface where blood-serum is constantly transuding or exuding over the ulcer or wound.

There are seven principal methods of skin grafting, namely: (1) Thiersch's method; (2) Reverdine's method; (3) Wolf's method; (4) pedicle flap intact; (5) pedicle flap not intact; (6) cuticle scrapings used while fresh; (7) old scrapings preserved in a bottle with normal saline solution and used when needed.

I do not desire to give the details of the seven methods which I have enumerated, for they can be obtained from a text-book. I desire to state in reference to these methods that they all have their advantages, but one great disadvantage—that of taking the grafts from the patient himself or from the volunteer if occasion should occur that a large amount is needed. All this can be avoided by the use of the amnion and the umbilical cord.

Before cutting the grafts, carefully look over the membranes for any abnormality or diseased portion. Observe whether there are any diseased parts or ulcerations, and question the patient from whom these organs are obtained as to her previous history. If such caution is observed there will be no chance of infecting the patient. After the organs have been found free from disease or abnormality they are placed in a bottle containing normal salt solution. Before placing the organs in the bottle containing the salt solution they should be immersed in warm water to wash away any of the vaginal excretion which they have taken up during its passage through the vagina. By keeping them immersed in normal saline solution and changing the solution a few times before the use of the organs they will keep alive for over seventy-two hours.

When the patient is ready for grafting the organs are dipped several times in a new solution of normal saline and then they are cut up into pieces in any shape and size desired.

The cord should be cut open and the blood-vessels scraped out. This is done so that the membrane which is to be used shall be free from any hindrance to its early union. The surface of the cord and amnion which is to be placed on the ulcer should be the continuation of the inner surface of the cord. The jelly of Wharton in the cord is of an alkaline reaction, and because of this fact it is easily absorbed and ultimately the membrane covering the cord is left on the surface of the wound.

The surface of the parts to be grafted must next be inspected. If there are undermined edges the edges should be cut away until healthy skin is reached. Then the surface is carefully cleaned and disinfected. If there are any exuberant granulations they should be leveled off to the skin. Then the surface is thoroughly asepticized. All bleeding must have ceased, whether the wound is recent or granulating. If oozing of blood persists the wound surface must be covered by a protective layer of rubber tissue, of silver foil, guttapercha tissue, oiled silk, or such like material, over which sterile gauze is applied and the skin grafting put off till next day. When on the next day the bleed-

ing has ceased the grafting should take place.

The area to be grafted should be cleaned thoroughly first with peroxide of hydrogen which is washed off with a bichloride solution of 1:1,000 or 1:10,000. After the use of the above the parts are next washed with decinormal salt solution. After thoroughly cleansing the area the grafts are placed over the wound carefully and smoothly.

When the whole wound is covered with grafts place over them oiled silk fenestrated so as to facilitate drainage. The next dressing should be ordinary sterile gauze and soaked in decinormal salt solution or Carrel's solution.

Over this gauze soaked with decinormal salt solution a damper or rubber tissue should be placed, so that the moisture may not evaporate. Over the damper more sterile gauze is placed and ordinarily dressed. The first dressing of sterile gauze should be daily changed and soaked in normal salt solution. In order that the grafts be not moved during the daily changing of the dressings, I place collodion around the fenestrated oiled silk. No antiseptic lotion should be used, only the saline solution. The same kind of dressings should be applied until the healing process is complete. Very large surfaces can be made to heal in a short time by this process.

I have tried this method on several of my patients and can confidently state that I have gained great success with it. I wish to suggest this method so that it can be tried by the surgeons when occasion should happen.

This idea came to me while I was on a maternity case. I said to myself that I was throwing away the refuse of nature, a tissue which could easily be utilized. After some time of experimentation with it I can claim that it is especially adapted for those cases in which the areas to be grafted are so large that enough grafts cannot be obtained from the patient himself. I wish to add in this preliminary paper a few cases which I have treated.

Case I.—Mr. R., aged thirty-seven, came to see me about an old ulcer, the result of a burn, which had been treated in private and in hospital without satisfactory result. He did not wish to have the skin from another portion of his body taken and grafted. He feared the pain which usually accompanies the operation and he feared that there would be a scar remaining after having his skin shaved off. The patient came to me on June 15, 1912. He had a burn extending over the greater part of his chest and a portion of his right arm. The next day I had obtained the necessities and ordered him to bed to prepare himself for the operation. After preparing the organs to be grafted and the burn of the patient very carefully, as if it was a major operation, I began to graft the cord and amnion. The grafts almost completely covered his burns, and I forbade him to rise without my orders. He remained in bed for two weeks and a half, at the end of which time I took off the dressings and oil silk. To my surprise, I could not find any remains of the grafts. There was only the circumference of the burn to be grafted, and this remained because I had not enough of the material at the time of the operation. To-day the patient is completely cured and the place where the burn was cannot be recognized.

Case II.—O., æt. eight, suffering with heart disease since birth. The child was scalded by hot water on the left cheek, entire arm, and a portion of the chest. She went to the hospital, where she remained until the acute symptoms had subsided. I treated the child at her home and to-day she has no scar on her person to remind her of having been scalded. While remaining in bed I took care of her heart and her condition has greatly improved. The cure was obtained in three weeks.

Case III.—On August 30 a man, fifty-seven years old, came to see me for treatment of varicose ulcer. Although it has taken longer than I had promised the patient for a complete cure, still my results were excellent. He returned to me for a similar condition on his left leg and another on his right leg. This patient I have yet under my care.

Case IV.—A young girl of about eighteen years old who while coasting last winter struck her leg against a curbstone. The consequence was a traumatic ulcer. She was successfully treated by fetal membranous grafts and recovered in a short time.

Case V.—A laborer who had received a blow with a crowbar over his left leg. The resulting ulcer was treated successfully with fetal membrane grafts.

2480 Arthur Avenue.

## Medicolegal Notes.

**Revocation of License—Complaint.**—The Oregon State Board of Medical Examiners has, by statute, authority to revoke a license to practice medicine and surgery for unprofessional or dishonorable conduct, subject to the right of appeal. The statute declares that the term "unprofessional or dishonorable conduct" means, among other things, the procuring, or aiding or abetting in procuring, a criminal abortion. It provides that before revoking the license a complaint under oath must be filed charging the acts of unprofessional or dishonorable conduct and facts complained of, in ordinary and concise language. A complaint against a physician accused him of unprofessional and dishonorable conduct, consisting of wrongfully and unlawfully procuring and aiding and abetting in procuring a criminal abortion upon a pregnant woman specified by means unknown. It was held that the complaint was defective in stating a mere legal conclusion that the defendant was concerned in procuring a criminal abortion, but not stating facts sufficient to authorize the court to make the same deduction that the action of the defendant was criminal.—Board of Medical Examiners v. Eisen, Oregon Supreme Court, 123 Pac. 52.

**Dissection on Coroner's Notice—Physician's Rights.**—Action was brought against a physician for alleged illegal dissection of the plaintiff's son, who had died in a hospital from injuries received in the street in a manner unknown. It appeared that the defendant had been requested by the coroner to make an autopsy, which he did. The New York statute provides that, on the death of any person in the city of New York, from criminal violence, by casualty, or suddenly when in apparent health, or when unattended by a physician, or in prison, or in any suspicious or unusual manner, the coroner shall subpoena one of the coroner's physicians, who shall view the body externally or make an autopsy, as the case may require. It was held that a formal subpoena was not indispensable to the protection of the coroner's physician. The fact that the coroner actlually directed the dissection of the body, and a microscopical examination of the deceased's spleen, was a complete defense to the action.—Hassard v. Lehane, New York Appellate Division, 135 N. Y. Supp. 711.

**License to Practise.**—The Washington statute provides that, in the case of a refusal of a license by the board of medical examiners, the board shall file a brief and concise statement of the grounds and reasons for such refusal in the office of its secretary, to remain, with the board's decision in writing, of record in said office. It appeared that the decision refusing the application of an applicant to practice osteopathy had been lost from the files or misplaced. It was held, in proceedings to compel the board to act upon the application anew, that the loss did not entitle the applicant to require the board to act upon his application as if in the first instance. Nor did the failure of the board to notify him that a license had been refused him entitle him to a rehearing on his application.—State v. Witter, Washington Supreme Court, 123 Pac. 471.

## RECENT STUDIES ON ORTHOSTATIC ALBUMINURIA.

ONE of the most interesting and at the same time puzzling conditions found chiefly during the adolescent period is that designated variously as functional, cyclical, paroxysmal, or orthostatic albuminuria. The multiple nomenclature is ample evidence of the obscurity that veils the real cause of this phenomenon. Attempts have been made to explain the latter on the basis of supposed organic changes in the kidneys akin to those of chronic nephritis, of vasomotor derangements in these organs, or of traumatic influences. Whatever the causation, the discovery of even a slight and intermittent albuminuria in an otherwise healthy though somewhat neurasthenic adolescent, is frequently the cause of considerable concern to the parent and physician, and of an unjust discrimination on the part of public physical examining boards and of life insurance companies.

A careful study of certain clinical and experimental aspects of this question has recently been made by V. Gomolitsky, who reports his results in the *Zeitschrift für klinische Medizin*, Vol. 77, Nos. 1 and 2. His investigation was prompted by the observations made by Schreiber and Shebrowsky, namely, that palpation of the kidneys in subjects in which these organs are movable causes a slight and transient albuminuria. The experiments of Gomolitsky were carried out in the Medical Institute for Women in St. Petersburg. In thirty-five cases of nephroptosis he applied various mechanical insults to the kidney, such as palpation, compression, vibratory stimulation through the abdominal wall, shaking of the entire body, making the patient walk rapidly up and down the room with or without an abdominal binder, and subjecting the region of the kidney to the action of cold and of the galvanic and faradic currents. In twenty-seven of the thirty-five cases repeated palpation of the kidneys did not give rise to albuminuria, nor were any of the other mechanical stimuli more effective in evoking this condition. The existence of a "palpatory albuminuria" may therefore be questioned in the light of these observations.

The explanations of the cause of orthostatic albuminuria have been numerous. Heubner attributed this condition to a general bodily weakness and anemia, while Senator and others perceived in it an expression or sequence of distinct nephritic processes. Von Noorden regards it as the result of changes in the blood—as a "diabetes albuminosus." Hauser believes that the albuminuria is the result of the action of toxic metabolic products upon kidneys already damaged by some infectious process. Teissier and Martin have alluded to the frequent coincidence of orthostatic albuminuria and tuberculosis. Turettini, Marie, and Teissier have noted a neuropathic element, a close analogy with migraine being pointed out by Marie. Von Leube believes that the basic cause of orthostatic albuminuria is cardiac insufficiency associated with anemia and a tendency to venous congestion. Edel, Pribram, and others seek to explain orthostatic albuminuria on the basis of vasomotor disturbances. The theory which has won most acceptance has been that advanced by Jehle, namely, that a spinal lordosis in the lumbar region is the efficient cause of orthostatic albuminuria.

The important observation has been made by Gomolitsky that in cases of scarlet fever orthostatic albuminuria is a common occurrence. The same is true of a number of other infectious diseases, notably typhoid fever, relapsing fever, lobar pneumonia, and chronic pulmonary tuberculosis. Orthostatic albuminuria bears no relationship to the degree of blood pressure or to the pulse rate. It has been shown that traumatism plays no rôle as a causative factor. The real cause is perceived in a functional incapacity of the kidneys, of hereditary origin, or sequent to any cause debilitating the entire organism, such as infection and the intensive growth of the body during the period of adolescence. A toxic agent affecting the kidneys is regarded as constituting the predisposing cause, while the exciting cause is held to be a functional impairment of these organs following the assumption of the erect posture.

A number of other important problems in connection with this subject await solution. The significance of venous stasis in the kidneys, and its relationship to lumbar lordosis, and the influence of this distortion upon the kidneys, upon their position and upon their nerves and blood vessels, are not the least of these problems.

## INSANITY AND THE NEUROPATHIC INHERITANCE.

WHAT is the relation of insanity to the so-called neuropathic inheritance? In a paper read before the Royal Society of London, on January 28, 1913 (*Lancet*, February 8, 1913), Dr. F. W. Mott attempts to supply an answer to this question. He points out that there are individuals born of sound mental and physical stocks that no acquired conditions, disease, drink, poisons, either engendered within the body or taken from without, head injuries, emotional shock, distress, and even profound misery and destitution combined, could render insane. There are others, and these are in most cases derived from a neuropathic stock, whose mental equilibrium might be disturbed by any of these conditions, or even without any apparent cause,

except the physiological conditions appertaining to the functions of the sexual glands at puberty, during adolescence, the puerperium, lactation, and the climacteric in women. Mott says every case of insanity should be regarded as a biological problem, and study resolves itself into the acquirement of a knowledge of what the individual was born with—nature, and what happened after birth—nurture. The former of these could be ascertained by a study of the ancestral stocks. Just as bodily features are transmitted from one generation to another, so is temperament. As for degeneration, Morel has drawn attention to the fact that nervous, irritable weakness and neurasthenic predisposition might be the first evidence of degeneration of a stock. The signs of degeneracy might be manifested as self-centered narrow-mindedness in religious beliefs, fanaticism, mysticism, spiritism, and unwholesome contempt of traditional custom, social usages, and morality, a vain spirit of spurious art and culture, a fake self-loving vanity in the pursuit of sentimental altruism, the intelligence being well preserved.

Mott, while considering that such qualities might be combined with latent or active genius, concludes that the brilliant intellectual qualities of a degenerate are generally associated with a lack either of moral sense or of sound judgment and higher control. Notwithstanding this view, however, Mott declares that the world's history has been made by men who were either epileptics, insane, or born of neuropathic stock. For instance, Alexander the Great, Julius Cæsar, Napoleon, Peter the Great, Frederick the Great, Pitt, Mahomet, the Apostle Paul, Martin Luther, Emanuel Swedenborg, and others. Among English poets, Cowper, Wordsworth, Byron, Gray, Burns, Chatterton, and Thompson were either insane or possessed the neuropathic temperament. Mott, therefore, seems to be of the opinion that genius is to madness near akin, and that insanity and neuropathy are in many instaces closely allied. Degeneracy on a large scale is a curse, but genius, if not a blessing to the possessor thereof, is a boon to the race at large. Without the neuropathic taint it is possible that there might be no geniuses, but with degeneracy rampant a nation must decay. Consequently, it would be madness to encourage or permit degeneracy because by so doing geniuses might be bred, for it must be borne in mind that while few degenerates are endowed with the divine spark, many of them are mentally, physically, and morally a bane to the race. Better it will be to uproot degeneracy as far as is possible, even if some brilliant brains are lost to the world thereby. In any avent, city environment should be improved by all the means in our power, as it is in the crowded cities that the worst type of degenerate is evolved. And after all, environment is a powerful factor in the manufacture of this product of civilization.

## "FAIRNESS TO A FOREIGN SCIENTIST."

Under this title *The Sun* of this city, a journal usually as well informed as it is fair minded in matters medical, uses the Friedmann episode as a text for some hard sayings regarding the profession in general and medical societies and journals in particular. In the first place the writer says that the press of the country has not been fair to Friedmann, "being misled by the violent opposition of a large majority of our medical journals and the action of some of our medical societies." We have read all that the leading medical journals of this country have had to say regarding Friedmann and his alleged remedy for tuberculosis, and while we have noted a tone of healthy scepticism in most of their editorial comments, we have never seen any evidence of "violent opposition" to him or his cultures. The Medical Society of the County of New York insisted that a trial of the remedy should be made in the proper way in the hospitals, and not (at so much per) in a private office, and the Medical Record and its contemporaries have maintained that such was the correct mode of procedure. But, as we remarked last week, the fact that Dr. Friedmann had tried at first to come in on the money basis, charging patients a fee for the privilege of being experimented upon, should not be allowed to prejudice the profession against his remedy which might on fair trial prove to be of therapeutic as well as commercial value.

The writer in *The Sun* is seemingly offering a defense of Friedmann's secrecy regarding the nature of his vaccine, but he does the man a bad turn when he casts slurs on the medical profession. "To the average reader," he says, "medical ethics appear to aim at the protection of medical men rather than the welfare of the public." He adds: "This is a fallacious idea," yet proceeds immediately to argue that such is the fact, for he says: "The beneficent influence of the 'Hippocratic oath' happily still sways the medical mind; and to this fact must be attributed the seeming indifference of the true physician to the interests of the patient when a question of ethics is involved." The opposition to Friedmann in Berlin, he adds, was due to the fact that he would not reveal the secret of his alleged remedy, and arose not so much from apprehension of harm to the sick as from fear that the good name of German science would be smirched by the exploiter of the remedy.

We commented last week on the troubles that had come to Dr. Friedmann, seemingly through bad advice. The poor man is now in danger of being prejudiced still more in the minds of his colleagues through the arguments of his supporters—if their only defense of him is to be an attack on the medical profession of this country.

## Army Surgery in the Balkan Campaign.

Very recently Professor Küttner of Breslau delivered a most interesting address on modern military surgery at the Postgraduate Medical School in which he utilized results from all recent warfare by land and sea. At a recent meeting of the Royal Imperial Medical Society of Vienna, Professor Exner gave an address on the military surgery of the current Balkan-Turkish war (*Münchener medizinische Wochenschrift,* February 4). The author has been in charge of the reserve hospital at Sofia, whither the wounded were conveyed in six-day marches in ox carts. They reached their destination exhausted and poorly nursed. There was an unusually large proportion of infected bone fractures, of which the milder types healed, as a

rule, promptly under immobilization. In all the author was called upon to supervise the treatment of 1,200 soldiers. Of twelve cases of tetanus but two survived. The victims might have been saved by superior transportation. There was not as much difference in the morbidity of infantry and artillery wounds as one usually expects, which is explained by the supposition that the latter were not as dangerous as usual. The worth of the conservative treatment of these wounds was borne out over and over. This holds good chiefly for infected wounds in which prompt opening and drainage were practised. There were but few cases of bullet extraction. There were over 80 cases of shot wounds of the lungs, which were not infected and but few were disturbed. Injury to both lungs gave a bad prognosis. In general the surgical resources of the Balkan allies were much below the European standard.

### Misinterpretation of Symptoms.

If a child of 13, undoubtedly syphilitic at birth, should present dystrophic alterations in the skin and teeth, few physicians would be circumspect enough to think of any other etiology for these anomalies. The dry, harsh skin and Hutchinson's teeth were indeed once regarded as pathognomonic of inherited syphilis, and have readily been explained by arrested growth due to injured germ plasm. But suppose it is learned that the child comes of a family which has been afflicted for several generations with this very same dystrophy? This experience occurred to Christ as related by him to the Wiesbaden Medical Society last December (*Berliner klinische Wochenschrift,* February 10). The dystrophy was therefore much more deeply seated than if syphilis had been the cause. Even the ozena which had been present for years was better explained as a feature of the dystrophy than as syphilitic. The child had given a negative Wassermann for at least two years. The discussion which followed showed the growing belief that antenatal deformities depend on an antecedent insufficiency of the glands of internal secretion. The connecting link between the former and the actual anomalies is seen in the sympathetic system. A peculiarity of the author's case had been mentioned —a certain sparing of the trifacial area in which the anlage for hair was recognizable. This very area is better innervated by the sympathetic than any other. Herxheimer, who examined various sections of integument, found no sign of sweat or sebaceous glands or hair follicles or arrectores pilorum. All the other tissues of the integument were underdeveloped.

### Nature of Epistaxis in Childhood and Youth.

This phenomenon, occurring as it does in a large proportion of growing individuals, from the outset of the "second infancy" of the French—which coincides roughly with the period of school years—has usually been regarded as developmental in character, a common disorder of daily life, like headache or constipation, which becomes pathological only when it cannot be arrested by ordinary means. Naturally there are other components, either exciting causes of traumatic nature or vague predisposing elements, such as mouth breathing and its various causes. Syphilis is to be thought of in severe repeated cases, likewise, of course, hemorrhagic diathesis. At a recent meeting of the local medical society at Chemnitz (*Münchener medizinische Wochenschrift,* February 3, 1913) Nobis took up the subject of nosebleed in youth as one more or less neglected or sidetracked in one respect, to wit, prognosis. Nosebleed in a child or adolescent is a habit which often persists for a decade or more. If the loss of blood is insignificant nothing need happen. But if the nosebleed is of frequent occurrence, so that the loss of blood is considerable, the resistance of the subject to disease is notably decreased. Not a few cases of tuberculosis may be traced to this source. Attention is called to the fact that nosebleed subjects eat most heartily in the evening so that during the night they tend to sleep and digest poorly. They awake with coated tongue and repugnance to food of any kind. The author advises a toilet of the nose, a pushing of good food early in the day with a light meal at night. The suspicion of a syphilitic taint often justifies the use of iodides, which involves abstinence from fruit and sweets.

## News of the Week.

**The Education and Training of Cripples.**—A sectional meeting on crippled children was held in connection with the Conference on Industrial Education for Children in the Assembly Hall of the Metropolitan Building, New York City, on March 8, 1913. This was the first occasion of the consideration of the special needs of cripples by any general conference. Mr. Douglas C. McMurtrie presided at the meeting and spoke of the historical development of care for the deformed and the experience in connection with trade training both in the United States and abroad. Mr. Charles H. Burr, superintendent of the city hospital and country branch of the New York Orthopedic Hospital told of the lessening necessity for industrial education in the work of his institution, this being due to the early ages at which they were getting their patients. With young children the chief need is for primary instruction. Dr. Charles H. Jaeger discussed the industrial training provided for adult cripples at the Trade School of the Hospital of Hope. Miss Florence Sullivan, in reference to the experience at the trade school for crippled boys and girls maintained by the Brearley League, spoke of the difficulty of getting as pupils boys and girls who were willing to give up enough time to take advantage of a full course. Miss Evelyn Goldsmith told of the need for industrial training for the graduates of the special classes for cripples in the public schools. Among those taking part in the discussion were Miss Catherine A. Bliss and Miss Edith Bond of the Association for the Aid of Crippled Children, Miss Reed of the social service departmnet of the New York Orthopedic Hospital, and Miss Janet Daniels, secretary of the Federation of Associations for Cripples. A resolution was adopted that the section be continued annually.

**The Friedmann Culture.**—After a long series of promises and withdrawals, three patients were actually treated by Dr. Friedmann with his tuberculosis "cure" on March 6 at the Peoples' Hospital, New York, on March 8 a number of other patients received the treatment privately, and the following day more were treated at Mt. Sinai Hospital. The hotel at which Dr. Friedmann has been staying, the offices at which, according to announcements, he would be prepared to give treatment to all-comers, and the hospital where he gave the first

treatment to carefully selected patients only, have been besieged by hundreds of wretched individuals, eager for help and ready to grasp at any hope. The matter has now been taken up by the Public Health Service, in whose hands the testing of the efficacy of the vaccine may safely be left, though no definite report can be made for some months. Surgeon General Blue has appointed Surgeon John F. Anderson and Passed Assistant Surgeon Arthur M. Stimson, to confer with Dr. Friedmann, be instructed as to his procedures, obtain samples of his culture, if possible, and conduct experiments in the Hygienic Laboratory. They will also keep under observation the patients treated by Dr. Friedmann. If the latter, therefore, lives up to his promises, some authentic report as to the value of his treatment may be expected. He has been lecturing and trying his remedy this week in Canada, where he appears to have made a favorable impression.

**City Death Rate.**—The death rate in New York City remains higher than the record established last year. For the week ending March 1, the rate was 16.50 per thousand, as compared with 15.50 for the same week of last year, while the total number of deaths was 1,699 as compared with 1,546. To the greater prevalence of influenza is ascribed the increase; and as compared with last year there were 105 more deaths from pneumonia, 40 more from Bright's disease, and 37 more from organic heart disease. The mortality of children under one year of age was slightly decreased.

**Dr. O. V. Huffman,** Secretary of the New York State Board of Medical Examiners, has been elected Secretary-Treasurer of the Federation of State Medical Boards, a national organization which will undertake the task of securing uniform legislation in regard to medical education and medical practice throughout the States.

**Dr. Fordyce Appointed.**—The Trustees of Columbia University, at their meeting on March 3, on the recommendation of the Medical Faculty, appointed Dr. John Addison Fordyce as professor of dermatology in the College of Physicians and Surgeons, succeeding Prof. George T. Jackson, resigned.

**Crocker Research Fund.**—Provision for the housing of the workers under the George Crocker Special Research Fund is to be made by Columbia University shortly in the erection of a small laboratory on East Field of the University. The new building, which it is hoped will be ready for occupancy in the late summer, is to measure 40 by 100 feet, and to consist of three floors and basement. Heretofore, workers under the Crocker Fund have been scattered through the various departments of the College of Physicians and Surgons and the need of a special laboratory for them has been greatly felt. The Fund, which amounts to about a million and a half of dollars, has been placed under the direction of Dr. Francis Carter Wood.

**Contagion in Schools.**—Supt. Maxwell of the New York City public schools, has recently issued a circular calling attention to the fact that a principal may bar from school a pupil suffering from contagious disease without waiting to secure a certificate from a physician of the Department of Health.

**Dispensary Statistics.**—The report on dispensary abuses made to the New York County Medical Society by its committee has called forth many denials and some interesting statistics. Secretary Hebberd contends that the alleged abuses are not under the control of the State Department of Charities and that the enforcement of the law is not in its hands, and, moreover, that the conditions have been exaggerated. Mr. Hebberd also contends that there has been much improvement within the last few years. In 1898, there were in New York City 123 dispensaries, which treated 1,052,177 patients, who received 2,189,655 treatments, representing 14.86 per cent. of the population; while in 1912, there were 99 licensed dispensaries, which treated 843,724 patients, who received 2,691,497 treatments, representing 8.81 per cent. of the population. The present law governing dispensaries was enacted in 1899.

**Dr. S. Weir Mitchell** of Philadelphia was the guest of the Milwaukee Medical Society at its meeting on February 27.

**Gifts to Charities.**—The Montefiore Home and the School for Crippled Children, New York, receive $1,000 each by the will of the late Mr. Alexander Sinsheimer of this city. Lebanon Hospital, Beth Israel Hospital, New York, and the Jewish Hospital in Worms, Germany, share in the residuary estate, the value of which is not stated.

**Jacobi Fellowship.**—As previously announced, the Woman's Medical Association of New York offers the Mary Putnam Jacobi Fellowship of $800, available for post-graduate study. It is open to any woman graduate of medicine. Applications for the year, beginning October 1, 1913, must be in the hands of the Committee by April 1, and the award will be announced by June 1, 1913. Further information may be obtained from the Chairman of the Fellowship Committee, Dr. Emily Lewi, 35 Mt. Morris Park West, New York.

**Experimental Surgery.**—A new laboratory for the use of workers in experimental surgery, has recently been opened at the Flower Hospital and Medical College, New York, under the direction of Dr. A. L. Soresi, professor of experimental surgery. Special courses will be offered to graduates in medicine.

**Rabies Epidemic.**—Reports of an epidemic of hydrophobia in Palestine have been received and it is stated that Mr. Nathan Straus of New York will shortly establish a laboratory there for the treatment of the disease by the Pasteur method.

**Smallpox in Hartford.**—Five cases of this disease in the Hartford Hospital, Hartford, Conn., have made it necessary to quarantine the institution.

**Nurses Graduate.**—Eighteen women received diplomas last week at the annual commencement exercises of the Lebanon Hospital Training School for Nurses, New York.

**Tennessee State Medical Association.**—The annual meeting of this association will be held in Nashville on April 8, 9, and 10.

**A Symposium on Tuberculosis of the Urogenital Tract.**—The next meeting of the Section on Genitourinary Surgery, of which Dr. Walter Brooks Brouner is Chairman and Dr. Joseph Francis McCarthy, Secretary, will be held March 19, at 8:30 P. M., at the New York Academy of Medicine. In addition to the reading of papers there will be a pathological exhibit of specimens of tuberculosis of the urogenital tract. The papers of the evening will be as follows: "Debatable Factors in the Surgical Discipline of Renal, Ureteral, and Vesical Tuberculosis," by Dr. Martin W. Ware. "Tuberculosis of the Epididymis; Its Effect upon Testicle and Prostate," by Dr. J. Dellinger Barney of Boston. "Urinary Findings in One Hundred

Cases of Tuberculosis of the Urogenital Tract," by Dr. Frederic E. Sondern.

**The Notification of Venereal Diseases.**—The Harlem Medical Association has passed a series of resolutions condemning the action of the Board of Health regarding the notification of venereal diseases. It says "the proposed 'administrative supervision' of venereal diseases by the Board of Health is inopportune, useless, dangerous, and opposed to the best interests of the public and the medical profession; that the enforced notification of the name and address of any patient suffering from venereal disease, as well as the presumed source of infection, is a direct violation of the professional secrecy which should ever exist between patient and physician; . . . . that no matter how secret or confidential a public city department may intend to keep such knowledge . . . . there will ever exist the greatest danger that knowledge of such diseases might be secured and carried directly within the family circle, where it would strike a blow at the very foundation of our social fabric by separating husband and wife, as well as degrading their social and commercial usefulness in the community." The association therefore protests against the enactment or enforcement of any order relative to the reporting of cases of venereal diseases to the Board of Health, and begs the Mayor and the president of the Board of Health to take the steps necessary to prevent its being carried into effect.

**Medical Society Elections.**—Lying-In Hospital Alumni.—The officers of the Alumni Association of the Lying-In Hospital, New York, for 1913, are as follows: *President,* Dr. H. B. Blackwell; *Vice-President,* Dr. M. L. Bradley; *Editor,* Dr. D. J. Hamburg; *Secretary-Treasurer,* Dr. C. Frederic Jellinghaus.

Cherokee County (S. C.) Medical Society.—At the organization of this society at Gaffney on February 25 the following officers were elected: *President,* Dr. J. T. Darwin; *Vice-President,* Dr. Mason W. Smith; *Secretary,* Dr. Victor Roberts, Blacksburg.

Reading (Pa.) Medical Society.—The following officers were elected at the annual meeting on February 28: *President,* Dr. Walter Bertolet; *Vice-President,* Dr. J. Wagner; *Secretary,* Dr. Claude Bankes; *Treasurer,* Dr. Clara S. Keiser.

Laurens County (S. C.) Medical Society.—At the annual meeting held in Laurens on February 24 officers were elected as follows: *President,* Dr. J. H. Teague, Laurens; *Vice-Presidents,* Dr. Isadore Schayer, Laurens, and Dr. J. Lee Young, Clinton; *Secretary-Treasurer,* Dr. T. F. Klugh, Cross Hill; *Reporter,* Dr. J. L. Fennel, Waterloo.

Simpson County (Miss.) Medical Society.—Officers were elected at the annual meeting at Mendenhall on February 21 as follows: *President,* Dr. Chandler, Braxton; *Vice-President,* Dr. E. Kennedy, Magee; *Treasurer,* Dr. A. Norman, Braxton.

**Obituary Notes.**—Dr. John Davies Trezise of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1901, a member of the New York State and Kings County Medical Societies and the Greater New York Medical Society, and for many years connected with the Department of Health in Brooklyn, died at his home from pneumonia on March 4, aged 51 years.

Dr. George Fischer of Paterson, N. J., a graduate of the University of Wurzburg, Bavaria, in 1889, and a member of the American Medical Association and the New Jersey State and Passaic County Medical Societies, died at his home on February 22, aged 47 years.

Dr. Edith Barton of Scranton, Pa., a graduate of the Women's Medical College of Pennsylvania, Philadelphia, in 1902, and a member of the Pennsylvania State and Lackawanna County Medical Societies, died at her home on February 20.

Dr. George White McClure of Springfield, Mo., a graduate of the Rush Medical College, Chicago, in 1900, and a member of the American Medical Association and the Missouri State and Greene County Medical Societies, died at his home from tuberculosis, after a long illness, on February 17, aged 35 years.

Dr. George Albert Clark of Portland, Me., a graduate of the Medical School of Maine, Portland, in 1870, and a member of the Maine State and Cumberland County Medical Societies, died at his home after a long illness, on February 18, aged 66 years.

Dr. J. B. Shawgo of Quincy, Ill., a graduate of the Bennett Medical College, Chicago, in 1877, and a member of the Illinois State and Adams County Medical Societies, died in a hospital at Jacksonville, on February 19, aged 69 years.

Dr. John Anthony Hobson of Flushing, Ohio, a graduate of the Miami Medical College Cincinnati, in 1872, the founder and physician in charge of the Flushing Hospital, and a member of the American Medical Association and the Ohio State and Belmont County Medical Societies, died suddenly on February 21, aged 63 years.

Dr. Rush H. Dew of Salem, W. Va., died at his home on February 21, aged 70 years.

Dr. Edward Pardee Bucke of London, Ont., a graduate of the Western University, Medical Department, London, in 1899, died at his home from pneumonia, after a short illness, on February 15, aged 37 years.

Dr. Hamilton Graham of Kennett Square, Penn., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1892, died at his home on February 22, aged 43 years.

Dr. William I. Reese of Adamson, Okla., a graduate of the College of Physicians and Surgeons, Baltimore, in 1893, died and his home suddenly on February 14.

Dr. Herbert W. Ferry of Poland, O., a graduate of the University of Illinois, College of Medicine, in 1904, a member of the Ohio State and Mahoning County Medical Societies, and a veteran of the Spanish American War, died at his home from pneumonia, on February 14, aged 36 years.

Dr. Robert Alfred Moore of Durham, N. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1891, and a member of the North Carolina State and Durham County Medical Society, died at his home after a long illness, on February 18, aged 43 years.

Dr. N. Graham Shaw of Maysville, N. C., a graduate of the North Carolina Medical College, Charlotte, died at his home on February 13, aged 52 years.

Dr. Alfred James Brown of Higbee, Mo., a graduate of the Bellevue Hospital Medical College, New York in 1877, died suddenly at his home on February 18, aged 56 years.

Dr. Michael H. Foy of Yonkers, N. Y., a graduate of the New York University Medical College in 1898, a member of the Jenkins Medical

Society, and attending physician to St. Joseph's Hospital, died in the hospital on March 5, following an operation for appendicitis, aged 39 years.

Dr. John Warren Willis of Waltham, Mass., a graduate of Harvard Medical School, Boston, in 1861, and a member of the Massachusetts State and Middlesex County Medical Societies, died recently at his home, aged 81 years.

Dr. Charles B. Holmes of Rahway, N. J., a graduate of the New York Homeopathic Medical College and Hospital in 1874, four times mayor of Rahway, and an active member of the Board of Trade, died recently at his home, aged 64 years.

Dr. Frederick C. Johnson of Wilkesbarre, Pa., owner of the Wilkesbarre Record and formerly one of the editors of the Chicago Tribune, who was graduated from the Medical Department of the University of Pennsylvania in 1882, but relinquished his profession to take up journalism, died at his home on March 4, aged 54 years.

Dr. Thomas Knowlton Marcy of Poquonock, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1860, died at his home on March 2, aged 78 years.

Dr. John W. Dal of Chicago, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1878, and a member of the American Medical Association and the Illinois State and Cook County Medical Societies, died on February 13, after a long illness, at West Olive, Mich, aged 58 years.

Dr. Jesse T. Dunn of Louisville, Ky., a graduate of the University of Louisville, Medical Department, in 1890, a member of the American Medical Association and of the Kentucky State and Jefferson County Medical Societies, and formerly a member of the faculty of the Medical Department of Kentucky University, died in the Jewish Hospital, Louisville, from pneumonia, after a short illness, on March 1, aged 45 years.

Dr. James Edwin Clemens of New Orleans, La., a graduate of the University of Louisville, Medical Department, in 1881, died at his home on February 27, after a short illness.

Dr. Lewis E. Norris of Hampden Highlands, Me., a graduate of the Thompsonian College, Barbourville, Ga., in 1861, and a veteran of the Civil War, died at a hospital in Bangor, from pneumonia, on March 2, aged 76 years.

Dr. John M. Wakefield of Warren, Me., a graduate of the Dartmouth Medical School, Hanover, in 1875, and a member of the American Medical Association and of the Maine State and Knox County Medical Societies, died at his home suddenly on February 27, aged 61 years.

Dr. Merritt Allen Long of Lowell, Mass., a graduate of Tufts College Medical School, Boston, in 1905, and a member of the Massachusetts State and Middlesex County Medical Societies, died at the Lowell General Hospital from septic pneumonia on March 4, aged 35 years.

Dr. Lyman R. Woodson of Rushville, Mo., a graduate of the Ensworth Medical College, St. Joseph, in 1898, died at his home on February 27, just after being appointed to the position of physician in State Hospital No. 2, St. Joseph, at the age of 36 years

Dr. Edward E. Kitchen of St. George, Ontario, a graduate of the Toronto School of Medicine in 1865, and formerly chairman of the Provincial Board of Health, died at his home after a long illness on February 19, aged 66 years.

(From Our Regular Correspondent.)

HUNTER'S DAY—SCOLIOSIS—CONSTRUCTION OF MODERN HOSPITALS—CHOICE OF DOCTOR REFUSED UNDER INSURANCE ACT—NOTES—OBITUARY.

London, February 21, 1913.

Hunter's day (the 14th inst.) was celebrated in the accustomed manner at the Royal College of Surgeons. Sir Rickman J. Godlee, president, delivered the oration in the afternoon, and also took the chair at the dinner in the evening. In his oration he drew an interesting picture of Hunter among his friends, many of them celebrities of the period, also of his house, of which he showed a ground plan, and referred to its remarkable contents. Passing to his museum, he reminded the audience that Hunter was not only a man of phenomenal industry, but one endowed with the mania for collecting, who thought of money only as a means of crowding his house with works of art and his museum with specimens illustrating not only his novel views of physiology, but others interesting from their rarity or beauty. Sir Rickman then noticed some of the changes in the museum since it was bequeathed by the founder. Clift, who wrote descriptions, made drawings and dissections, etc., had been engaged without fee, and worked for about a year and a half when Hunter died. He was then retained at 7 shillings a week to catalogue and dust. When at last the government gave £15,000 for the collection, and subsequently a further £12,000, and the college gave £21,000 for the first building for it, Clift was made the first conservator, retiring on a pension in 1842, and was followed by Richard Owen, whose great work was the publication of the illustrated catalogue of the comparative anatomy series. Next came Queckett, who was essentially a microscopist, and made a microscope for himself out of a roasting jack, a parasol, and a few bits of iron. He left to the museum a valuable microscopic collection, and was succeeded by Flower, who, starting as a surgeon, became a pure anatomist, and greatly enriched the osteological collection. Then came Stewart, with excellent work on mimicry, symbiosis, and protective coloring. Now, under Dr. Keith, the aim of the college is to adhere closely to Hunter's principles, to regard his words "body, blood, and motion," as their motto to illustrate the processes of life. The president then pointed out that since its erection, in 1800, the museum had been more than trebled, and was certain to be still further enlarged. It now contains 64,766 mounted specimens. He illustrated its arrangement to show its harmony with Hunter's original conception, and then referred to the losses sustained by the college in the deaths of Mr. Dent, Sir Henry Bullin, and Lord Lister. As to the future, he asked if the country ought not to have an anatomical and pathological institute, forming part of a living university, of which the college would be the medical faculty, offering opportunities and the vast material of the museum for original research, and expounding in its lectures the advances made.

At the Polyclinic, in Cherries Street, on January 27, Mr. Muirhead Little of the Orthopedic Hospital, lectured on "Some Recent Advances in the Treatment of Scoliosis."

After a brief description of what scoliosis is, of its varieties, and causes, and of the difficulties which have on too many instances rendered treatment practically ineffective, the lecturer said that no doubt by long and continuous treatment, and by devoting most if not all the time of the patient thereto, marked and beneficial results had been achieved by various surgeons.

Such treatment, however, was beyond the reach of the greater number of cases attending at hospitals, and even beyond the reach of some classes of private patients.

The method introduced by Dr. E. G. Abbott of Portland, Maine, was almost startling in its simplicity. Mr. Little described this method and the apparatus which Dr. Abbott used in the application of plaster jackets.

The great innovation in the treatment lay in flexing the spine as much as possible, instead of attempting to correct the rotation or extension, as had been the practice of all surgeons hitherto. Although so far he had not yet succeeded in correcting such severe cases as those figured in Dr. Abbott's paper in the New York *Medical Journal* of April 27, 1912, this was probably due to lack of experience in the details of the method. At least, he was able to say that after a short experience in a few cases he had been able to effect much greater improvement, amounting in some cases to cure, than he had achieved by any other proceeding. In the lecturer's opinion very great credit was due to Dr. Abbott for his innovation, and he was to be heartily congratulated on his powers of observation and on the perspicacity which had led him to his conclusions, and the industry with which he had worked out the method.

On Tuesday evening, at the Royal Institute of British Architects, two papers were read on "Modern Hospitals," in both of which the difference between English, American, and continental plans were considered. Mr. A. Saxon Snell read the first, and said that whereas in England we concentrated on sanitary fittings, local cleanliness, and exclusion of soil-tainted air, on the continent better provision was made for space. The pavilion type adopted as a result of the Crimean War was again emphasized in the American and Franco-German wars. Two notable attempts in planning ward blocks had recently been made, (1) to substitute circular wards for pavilions; (2) to group all wards together. Mr. Snell attacked the niggardly areas provided for sites as in two of the latest and most magnificent (Royal Infirmary of Manchester, and King's College, London). He held that in and around cities, hospitals might be placed in the center of public parks, but mountains of prejudice would have to be overcome and all kinds of solemn nonsense would cry out. To secure a sufficiency of light and air, he said, the only method was to have one-story buildings, widely spaced on the site, and designed with few shadow-casting and air-obstructing projections. It would be well, too, for them to be raised above the ground on arches. The increased area required would only be about 30 per cent.

The second paper was by Mr. Milburn, who contrasted American and European construction by reference to some of the best-known examples. It was, he thought, for the medical rather than the architect profession to say whether the typical German general hospital was superior to the English. Foreign opinion held that the English, with all its excellent points, was inclined to be stereotyped in arrangement and planning of the ward unit, but the out-patient departments, and fever hospitals, were regarded as superior, and in the best examples the internal design, also. The Germans opposed more than 1,500 beds in one hospital. Mr. Milburn also said he did not consider the height of American and English hospitals objectionable. There was a tendency which he approved to decrease the large ward. The ideal, though practically impossible, was a separate ward and nurse for every acute case. He suggested building special pavilions for private patients, and strongly approved the American and continental practice of providing grounds and gardens. He hoped general hospitals would obtain suburban and larger sites.

Mr. E. T. Hall moved a vote of thanks to the two authors of the papers, and said the number of stories was governed by the site. A town hospital, surrounded by streets, might be as good as a country one. The essential was fresh air. With small wards nursing cost increased. He favored large wards, with small annexes for special purposes. Larger spaces per bed were less important where the open air system was adopted.

Dr. P. Boobbyer, seconding the vote, which enthusiastically carried, said that from introducing the system of free ventilation without artificial heating he had gone on to treating patients in open-air verandas, even pneumonia and scarlet fever with a temperature of 105°, without so far any untoward result. Artificial ventilation should be avoided as far as possible.

The insurance commissioners have issued a long memorandum to the committees, telling them that the right of patients to choose their own doctor, so often asserted by Mr. Lloyd George in his speeches, and provided for in the act, only applies to exceptional cases, and that they are to carefully consider each application. They say the majority of cases so far are for attendance by doctors not on the panel, and many can be met by those gentlemen coming on. Classes are not to be admitted as a whole, nor too many to choose the same doctor, as that would assist those setting up alternative services. The commissioners assert that the act does not mean what everyone understood it to mean. Heretofore it has been held that the only interpreters of the law are the judges. If commissioners appointed by the promoters of an act are to be allowed to assume the powers and authority of the judges the way is clear for any tyranny. The socialist papers are chuckling over the defeat of the doctors, and do not seem to see that similar trickery might be played upon themselves.

Sir W. Ramsay, presiding at the Institute of Sanitary Engineers on Monday, protested against the waste of time in discussing abstruse political problems which affected very few people, to the neglect of questions of sanitation, which affected everyone. He would have sensational legislation let alone, and time and energy devoted to sewage, water supply, housing, and other things conducing to the health and happiness of the people rather than to excitement which did absolutely no good.

Sir Ronald Ross, F.R.S., K.C.B., at the request of the Colonial Secretary, will visit Cyprus to investigate the causes of the prevalence of malarial fever on the island, and advise as to the means of combating the disease.

Army medical officers are to encourage soldiers by lectures, demonstrations, or as they think best,

to be inoculated against enteric—especially as they attain the age of liability for foreign service.

The death of another doctor "by misadventure" is the verdict of a coroner's jury. He had taken an overdose of morphia, being a sufferer from insomnia.

Sir Thomas Chavasse, senior surgeon to Birmingham General Hospital, died on Tuesday, in his 59th year, from heart failure. He had sustained a fracture of the femur from a fall in the hunting field shortly before Christmas, and had not regained his normal health. He graduated at Edinburgh, in 1878, and took the Fellowship of the Edinburgh College of Lawyers the same year. In 1899 the London College elected him a Fellow *honoris causa*. He was an esteemed authority on cancer, and contributed on various surgical subjects to the medical societies and journals.

## OUR BERLIN LETTER.

(From Our Regular Correspondent.)

DEATH OF CARL LÖBKER—PROTAGONIST OF THE RIGHTS OF GERMAN PHYSICIANS UNDER THE NATIONAL INSURANCE SCHEME—SCIENTIFIC AND PUBLIC ACTIVITIES—FRIEDMANN'S TREATMENT OF TUBERCULOSIS.

BERLIN, December 31, 1912.

A SHORT time ago there passed away one of the best known and beloved of German physicians. Last October Carl Löbker died after a prolonged illness. He was not a leading figure in the profession; nevertheless, everyone gave an attentive ear to whatever he had to say. Within recent years the opportunity to hear him occurred once annually, when he presided at the reunion of German physicians, and on this occasion he would review all that had touched the heart of the profession during the previous year. With undaunted courage he was able to grapple with problems that others feared to attack. During the first period of his activity as president of the German Medical League there occurred the inception of the national insurance scheme which has won and still retains the sympathetic interest of the profession. The truth has gradually dawned that the success of this scheme depended solely upon the hearty cooperation of the medical fraternity. But at the same time the interests of the physicians have been forgotten. It is becoming more and more manifest that the national insurance law of Germany has harmed the profession, both materially and ethically. The voice of the profession is now being heard. There has been organized in Leipzig a league of physicians who are seeking to accomplish by means of strenuous tactics what could not be attained in a peaceful way. The number of these physicians has grown, but in the beginning the campaign was so new that opposition to it arose in the inner circles of the profession. At this point Löbker threw the weight of his influence on the side of the reformers, and one of his greatest triumphs was his process in getting the entire German profession to adopt the cause of the Leipzig league. With indomitable energy and masterly politics he led the discussion of the physicians' rights before the general meetings. His activity knew no precedent; he threshed out even the minutest details of the subject under discussion.

This extraordinary man was born in Westphalia, 1854, the son of a school teacher. With his twelve brothers and sisters he was certainly not brought up in the lap of plenty. He graduated from the University of Greifswald in 1877. After having been an assistant at the Anatomical Institute, he was successively an assistant in the gynecological clinic and assistant in the surgical clinic under Hueter, with whom he was bound by ties of friendship. His writings, which were based upon his earlier anatomical studies, dealt chiefly with gallstone disease and bone surgery. His "Elements of Operative Surgery" won general acceptance. In 1889 Löbker was appointed director of the first hospital for traumatic surgery, which was established at Bergmannheil. He retained this position for twenty-three years, during which period he transformed the institution into a model of its kind. By means of his vast knowledge, his diagnostic skill and his excellent operative technique he succeeded in making the Bergmannheil hospital the surgical center in Westphalia. He was a good teacher, who made skilled surgeons out of his assistants, who were attached to him with unusual affection for many years. This confidence was reciprocal. For only one year before he died Löbker was operated upon for gallstones, under local anesthesia by one of his assistants. He commanded a large private practice. He took a lively interest in public affairs in his native town, became a member of the Municipal Council, and since 1904 presided over this body. He was a leading spirit in a phenomenally large number of learned organizations. He was a member of the scientific delegation of the medical profession of Prussia, a member of the National Board of Health, and a member of the national organization for professional postgraduate study. He was president of the Westphalia Medical Society and of its committees and of the Court of Honor. His greatest influence was exerted when he filled the office of president of the German Medical League. His death is mourned by the entire profession.

The treatment and prophylaxis of human tuberculosis was the subject of a paper read by F. F. Friedmann on November 6th before the Medical Society. With living tubercle bacilli obtained from the turtle he claims to have succeeded in producing an immunity to tuberculosis, and by means of two injections of these bacilli to have cured long-standing cases of tuberculosis. A number of physicians report good results with this method of treatment, which is said to be effective in cases not only of pulmonary tuberculosis, but also of surgical tuberculosis.

4. Observations on Recent Cases of Bladder Tumors at the Massachusetts General Hospital, with Special Reference to Operative Technique. R. F. O'Neil.
5. The Value of High Frequency Cauterization in the Treatment of Vesical Papillomata. H. Binney.

2. Tumors of the Bladder.—J. D. Barney emphasizes the fact that hematuria may be a sign of a very serious bladder disease; it should be looked upon with suspicion until its source and cause are clearly demonstrated. Moreover, one should combat the idea of the benign nature of bladder tumors. A very large proportion are malignant from the start in that they infiltrate the bladder wall and lead to metastases. Some that are apparently benign

in the beginning tend later to infiltrate. Some that do not show any tendency to infiltrate tend to multiply and destroy life by hemorrhage, sepsis, and interference with the renal function. Until one's knowledge of these tumors is greater one is taking too great a risk in assuming that any given bladder tumor is clinically benign, though one may have reason to believe that a few probably are. The only proper treatment for tumors of the bladder is their early and complete removal. In most instances this should be by excision.

3. **Tumors of the Bladder.**—A. L. Chute believes that too much stress has been put upon the non-malignant tumors of the bladder, which make up a very small proportion of all cases of bladder tumors. With the exception of a few pedicled prostatic masses, the author has never seen a tumor of the bladder that was not either actually or potentially malignant. The carcinomata and sarcomata are actually malignant; the papillomas, unless eradicated early and thoroughly, are in the vast majority of instances going to spread so as to involve a large amount of the bladder surface; and even when they are not actually malignant, they are going to undermine the health by hemorrhage and sepsis. This sepsis does not limit itself to the bladder, but often extends to the kidney, for with an infected residual of any considerable number of ounces there is going to be back pressure on the kidneys and, finally, pyelonephritis. The second point that has not been made sufficiently clear is in regard to the real malignancy of bladder tumors as a whole. One speaks about the malignant and benign papillomas, referring to their microscopical picture rather than to their clinical course. This gives to many men not especially familiar with them the impression that there is a class of bladder tumors that is really clinically benign. The author does not believe this is so, and believes that all bladder tumors are essentially malignant. Papillomata are not malignant in the sense that they infiltrate or lead to metastases, as the carcinomata and sarcomata do, but they are malignant in the sense that they proliferate locally and lead to danger through hemorrhage and infection of the bladder and kidneys.

5. **High Frequency Cauterization in Treatment of Vesical Papillomata.**—H. Binney finds that high frequency cauterization is an important addition to one's means of attacking vesical papillomata of the non-infiltrating type. If properly applied it is free from complications or danger with the exception of hemorrhage; this appears, however, to be rarely serious or troublesome. High frequency cauterization avoids the danger of multiple recurrences such as occur not infrequently after suprapubic cystotomy. Although the author's cases so treated are too recent for absolute proof of cure, the results are highly encouraging.

8. Strangulated Hernia. H. Goldstein.
9. Chorea. P. H. Markley.

1. **Dementia Præcox.**—F. X. Dercum states that the term dementia præcox embraces the following conditions: hebephrenia, catatonia, and dementia paranoides. He reviews the essential features which are common to all of these three forms. First there is a gradual onset, usually of the character of a confusion, but sometimes possessing elements of systematization; second there is present in the early period of the affection hypochrondriasis and depression and in the later period expansion; third, in the majority of cases the affection is progressive and the mental impairment steadily increases and terminates in dementia. The mental state is best interpreted as a confusion. There are present, in general terms, the elements of a confusional insanity, *i.e.* there are present unsystematized, fragmentary, and unrelated delusive ideas, together with hallucinations. In some cases, *i.e.* the older or paranoid cases, there is present or there is an approach to systematization. Second, the patients pass from the depressive to the expansive stage. As a rule the transition is gradual. The features which distinguish the various forms from each other are briefly outlined as follows: As regards hebephrenia it may be stated, first, that the symptoms of dementia præcox are here generalized in type. The characteristics of the more differentiated forms, catatonia and dementia paranoides, are lacking; *i.e.* there are lacking more or less markedly, on the one hand, the special motor phenomena, the fixation, resistance, negativism, and verbigeration of catatonia, and, on the other hand, the systematized delusions of paranoid dementia. Second, as is well known and as was shown statistically by Pickett, hebephrenia is the form met with among the younger patients, *i.e.* the youngest group of all. Consequently, and as might perhaps be justly inferred, the degree of the emotional departures from the normal is less marked than in catatonia and paranoid dementia. Third, the delusive ideas are in hebephrenia wholly unsystematized, fragmentary, changeable, and transitory. In this particular the contrast is most marked with the paranoid form. The distinguishing features of catatonia consist in that there are added to the general symptoms of dementia præcox, definite motor phenomena, spasms, fixed attitudes, stereotyped postures, automatism, negativism, verbigeration, and stupor.

5. **Family Incidence of Malignant Tumors.**—G. L. Rohdenburg reports three examples of the types described by Behla and others. *Cancer à deux,* so called house infections, and family transmissions are all represented. It is known that irritation has a powerful influence in the production of malignant tumors. The three families to which the author's cases belonged were observed during the past six years. Viewed casually the cases apparently furnish evidence supporting the viewpoint of a parasitic etiology. Closer examination shows that irritation is the predominant element, and that combination in family groups and houses is incidental.

7. **Intramural Abscess of the Uterus.**—A. H. Harrigan believes that in order to form a correct conception of intramural abscess of the uterus and to retain its clinical entity, a rigid distinction should be made between it and uterine lesions occasionally seen during the progress of a pelvic thrombophlebitis. In the latter instance the abscesses are small and multiple, and result from the disintegration of venous clots, while in the condition under consideration the abscesses are usually single in number, lymphatic in origin, and mostly situated in one of the uterine cornua. Two explanations are offered for this predilection. According to Championnière, the intrauterine lymphatics converge toward the cornua. Also, as pointed out by Mercade, the embryonal prototypes of the uterus, the Müllerian ducts, occasionally persist in the cornual regions as vestigial structures. Possibly these two factors, the richness of the lymphatic vessels and the presence of fetal structures of diminished resistance, conduce to make this region additionally susceptible.

3. **Manganese Poisoning.**—L. Casamajor describes a syndrome observed by him among the workers in a separating mill connected with a large mine of which zinc is the principal product. Eighty-five different ores are found in this mine. One ore, a sesquioxide of zinc, iron, and manganese, comprises 54 per cent. of the ore body. Willemite, a silicious oxide of zinc, forms 21 per cent.; rodenite, silicate of manganese, forms 9 per cent., and the red oxide of zinc 4 per cent. The remaining 81 ores make up the other 21 per cent. in varying quantities. Lead and arsenic may be absolutely excluded as causative agents. Arsenic is absent and only very minute amounts of lead are present. In the separation of the crude ores the magnetic ones are removed by very powerful electromagnets in a dry state and further separation is done by a specific gravity method under water. The dust question is an important one, and, in spite of all the efforts to eliminate it and regulate the washing and changing of the clothes of the men, there is still a great deal in the air. Nine cases of poisoning have been observed and form the material for this paper. The symptoms are practically the same in all cases. They are principally marked festination with sometimes stiffness and pain of the legs and intention tremor. About half the patients have defective hearing not due to middle-ear disease. Asynergia is present in all the well-marked cases. There is never any rest tremor of the limbs. Sensibility is preserved as well as muscular power. The blood never shows the changes characteristic of lead poisoning. The speech in some of the patients is somewhat slurring. The urine and spinal fluid were negative in the cases in which these were examined, as was also the Wassermann reaction in five of the patients. The face has somewhat the mask-like character seen in paralysis agitans. There are no characteristic mental symptoms, though one patient showed defective intelligence, which has improved. One patient died of pneumonia and came to autopsy, and no characteristic gross changes were observed except large perivascular spaces in some of the basal ganglia of the brain. No patients have recovered. The author does not think that zinc can be held responsible, and believes that the cases resemble most those reported by Embden in workers in a manganese dioxide grinding-mill. He sums up his paper with the following conclusions: (1) This is a definite pathological condition, recognizable by a definite syptom-complex. (2) It is a pathological condition of the central nervous system affecting principally the mechanism of walking and equilibrium. It cannot be placed under the heading of any known central nervous system disease. It is of toxic origin and in greatest probability the toxic agent is manganese.

6. **Exercises in Treatment of Abdominal Ptosis.**—H. H. Oldenborg calls attention to contributions on the subject of abdominal ptosis and says that, while most writers have recommended gymnastic exercises, few have given directions as to how they should be performed. All agree that the abdominal walls are relaxed and that there are a more or less pronounced lumbar lordosis, round shoulders, flat-chestedness, and acuteness of the so-called epigastric angle attending ptosis of the abdominal organs. To correct these conditions it would consequently be necessary to strengthen the upper spine, develop the chest and increase lung capacity, strengthen the abdominal walls, and overcome the lordosis. There is not enough attention paid to predisposed children and to those that have inherited the weakness. Another class would be women whose abdominal walls have become relaxed from frequent pregnancies and those of both sexes who have acquired the condition on account of accident or the nature of their occupation. With children, good hygiene, plenty of outdoor air and regulated gymnastics during their school years would do much to lessen, or perhaps remove, the liability from inheritance or predisposition. After the physical development is complete the same means can be used, but the patients have less time and perseverance, and with these, according to the author's experience, one has the least success.

10. **Diabetes and the Removal of Tumors.**—M. Manges refers to the cases reported by Miller and Joslin of the disappearance of diabetes after extirpation of tumors of the uterus and reports two similar cases in which the glycosuria disappeared after prostatectomy. In one of the cases the disappearance was temporary, but in the other recovery seems to have been complete. It is well known that diabetes can be cured in exceptional cases without dietetic treatment, but this is most likely to occur when cerebral trauma or syphilis is the cause. Naunyn refers to cures of diabetes, usually in acute cases and largely in children, when organic disease cannot be diagnosed, but this result is not apt to occur when the disease is of long standing, and he warns one against considering as cures the not infrequent cases which become latent for varying periods. Von Noorden calls attention to the marked improvement that is sometimes seen on the occurrence of chronic granular nephritis and to the fact that he has found the blood richer in suprarenal extract in these cases. He conditionally attributes the improvement to this, the suprarenal extract stimulating the liver and pancreas and possibly causing hypertrophy of still intact islands of Langerhans. In the author's cases the diabetes long antedated prostatic symptoms and renal disease played no part. Unfortunately it was not noted whether any hyperglycemia existed, but this is not probable. The most plausible explanation, according to the author, is that the operation removes some nervous or toxic irritant which in some way, at present unknown, disturbs the carbohydrate metabolism. Of more importance than the theories of causation are the practical points involved. Surgeons have always dreaded operations in severe cases of diabetes, but these four cases would indicate that the prognosis from the operative point of view is far better than is supposed. One may even go further in hoping that the operation may have beneficial results in the diabetes itself if the excellent results in these four cases are observed by others. When diacetic acid or oxybutyric acid tests are negative there is no danger, no matter how intense the acetone reactions may be. If positive the prognosis should be more guarded. In such cases the physiological chemist can give definite information as regards impending coma by the determination of the relations of the ammonia nitrogen to the total nitrogen excretion in the urine. When this quotient is low and within normal limits the immediate prognosis is good and the danger from grave acidosis and coma is not sufficient to prevent any necessary operation.

8. The Therapeutic Action of Splenic Extract and its Application in the Treatment of Tuberculosis. H. R. Harrower.

2. **Experimental Poliomyelitis.**—J. McIntosh and H. Turnbull record their results in the inoculation of monkeys with the material obtained from four cases of human poliomyelitis. They suggest that in sporodic cases the virus is feeble, and the occurrence of the disease is due to a hypersusceptibility of the individual attacked, while an epidemic results only when the virus has become exalted either by a series of passages through susceptible individuals or from some other cause unknown. It seems probable that the virus has been gradually exalted during the last three years in the neighborhood of the London Hospital, until a mild epidemic occurred in 1912. It will, therefore, be of great interest to note whether the pathogenicity increases in 1913.

7. **Ptomaine-Producing Intestinal Bacteria.**—D. M. Bertrand and A. Berthelot conclude that the *Bacillus aminophilus intestinalis* has well-marked saccharolytic and aminolytic properties. Varying the different nutrient substances with the exception of the aminoacid, the microorganism may remove the carboxyl group; when this aminoacid is the only substance containing nitrogen and carbon, it is able to show both properties at the same time. It can get its nitrogen and carbon from various organic molecules. As this microorganism splits off carbon dioxide very easily from aminoacids in various conditions of media, it seems possible then, to try to supplement the few ideas we have at present on the production of ptomaines in the intestinal tract and to study their acute and chronic action in the human organism. The authors succeeded in obtaining from human feces two other bacteria, one of them rather different from the *Bacillus aminophilus intestinalis* formerly studied, which microorganisms can produce imidazolethylamine by the same process. It was, indeed, very probable that this bacillus was not the only one in the intestinal flora able to produce such an action. These microorganisms have only been isolated from patients suffering from chronic autointoxication with some intercurrent intestinal disorder. The point particularly interesting is that it has always been impossible to get a growth from feces of people enjoying very good health, exactly as happened in the cases in which the authors isolated formerly "tyrosinolytic" bacteria. They conclude that by the very simple technique proposed more than a year ago they have been able to isolate from the human intestinal tract microorganisms capable of producing a very active base—namely, β-imidazolethylamine—from histidine; further, its isolation does not require more than three days, and frequently one can obtain a pure culture in less than forty-eight hours.

8. **Therapeutic Action of Splenic Extract.**—H. B. Harrower notes that the use of splenic extract has been advised in several diseases, and believes not only on general theoretical and experimental grounds, but from actual clinical experience, that it is useful in tuberculosis, and that its value is presumably due to certain splenic hormones, on which, in a degree, the following phenomena are dependent: (1) The defences of the blood: leucocytosis, phagocytosis, and, possibly, hemoglobin formation, and iron metabolism. (2) Tryptic digestion, thus directly increasing assimilation and nutrition, permitting an increased intake of food, and indirectly relieving the emunctories from the excessive work common in toxemia and suboxidation. (3) Intestinal digestion and the production of enterokinase. (4) The process of healing, both as regards the prevention of hemorrhage and the stimulation of rapid connective tissue production. (5) Antagonism to the tubercle bacillus by an influence on its culture medium, due to the production of a certain colloid substance (Bayle). (6) And finally, the function of the spleen itself.

2. **Aches and Pains Connected with the Eye and Nose.**—C. E. Shaw notes that pain in the eye itself, increased by every movement and accompanied by redness and watering, is often due to a foreign body in the eye. Sharp neuralgic pain coming on every night for weeks or months and hindering sleep is not uncommon. It is not only in the eye, but around it and shoots over the top of the head and down the side of the nose, and may affect one or both eyes. Such pain points to chronic iritis and is important to recognize if vision is to be saved. A somewhat similar, but often more severe pain, coming on with marked signs of irritation—injection, photophobia, and lacrymation—and a dull muddy look in the iris, with contracted pupil and little or no loss of vision, indicates acute iritis, commonest in young adults. It is easily mistaken for simple catarrhal conjunctivitis, in which there may be similar signs of irritation, but the diagnosis is made by observing that the pain is worse in iritis, and is not confined to the eyeball, and also in iritis the pupil is sluggish or immovable. Further, in conjunctivitis there soon appears a sticky secretion, which is absent in iritis. The same acute pain and irritation, coming on suddenly in a person over fifty, with dilated pupil and great loss of vision, indicates acute glaucoma. In this case the pain is proportionate to the vascular disturbance, and may be agonizing and accompanied by vomiting. Gout in the eye is not common, but it is well to remember that it may occur, and be very alarming. It comes on suddenly at night with great pain in the eyeball, which is acutely congested and irritable; but the pupil is clear and moves freely, and vision is not affected. A very severe bursting pain, generally described as in the middle of the head, but sometimes shooting up to the ears, with marked constitutional symptoms, is caused by suppuration in the sphenoidal sinus. Constant or frequently recurring pains rather vaguely localized about the back of the nose and shooting up into one or both ears, especially if occurring in an elderly person, call for careful examination, as they may be due to malignant disease. Hypertrophy or cystic enlargement of the middle turbinated bones is a fairly frequent cause of headache in young adults. Chronic suppuration in the accessory sinuses is a frequent cause of headaches. The severe and continuous headache which is caused by tumors, gummata, etc., in the brain has no direct connection with the eyes. The commonest cause of headache is an error of refraction, especially astigmatism.

7. **Operative Treatment of Hydrocele in Infants.**—J. H. Nicoll states that hydrocele in infants may be safely and effectively operated upon in the dispensary. The method he employs is the following: A skin incision (1 to 1½ inches) is made just above the groin over the inguinal canal, and the spermatic cord is exposed just below the ring. The testicle and hydrocele are pushed

up into the wound, and the upper end of the hydrocele sac is exposed by a few snips of the scissors. The exposed sac is then emptied by trocar and cannula. The collapsed sac with the testicle are then pulled out of the wound, and the sac is dealt with either by tearing out its internal serous lining, by complete excision, or by bisection and suture of its halves back to back behind the testicle. Replacement of the testicle in the scrotum, and suture of the wound in the groin complete the operation.

9. **Vaccine Treatment.**—H. T. Gillett believes that when failure occurs in treatment by vaccines the question should be considered whether the failure is due to the patient's feeble powers of response, or to the method of preparation and dosage of the vaccine. With this in view one would pay particular attention to the following points: (1) Make sure what microorganism is the cause of the trouble and whether others are associated with it. (2) Use an autogenous vaccine in preference to an heterogenous one. (3) Make it up from fresh material; try different media for its preparation; grow the microorganism for not more than twenty-four hours if one can get sufficient growth in that time; avoid subculturing as far as possible; sterilize by heating to 60° C. for a quarter of an hour instead of one hour, or in some cases merely by the addition of 0.5 per cent. carbolic. (4) Give doses large enough to produce a reaction but avoid a prolonged negative phase. Though vaccine therapy may be said to be still in its infancy, it has already achieved a great deal, both in the prevention and cure of various bacterial diseases. And now that serum therapy can be combined with vaccine therapy by giving sensitized vaccines, it seems probable that in the future it may accomplish still more, especially in acute cases such as pneumonia and septicemia, and will eventually largely replace the treatment by drugs in those diseases which are caused by microorganisms.

10. **Supraclavicular Anesthetization of the Brachial Plexus.**—W. F. Neil and F. Crooks state that this form of anesthesia was first brought to notice by Hirschel in 1911, and later in the same year an article was written by Kulenkampff giving an account of 100 cases. Early in 1912 Borcher published the results of thirty-five cases; since then the method has been used extensively on the Continent. It is convenient, appears to be free from danger, and by its use severe operations on the arm can be performed painlessly and without shock. The technique of the injection is easy after a little experience. The brachial plexus is injected at a point which roughly corresponds to the middle of the clavicle. Here the plexus lies close under the skin, so that in many cases its position can be defined by pressure over the first rib. It emerges from under the scalenus anticus muscle, and lies in loose tissue which is easily infiltrated. The area into which the solution is injected is bounded internally by the subclavian artery, externally by the clavicle, and below by the first rib. Definite paresthesia in the arm or hand must be obtained before any solution is injected. The injection should consist of 20 c.c. of a 2 per cent. solution of novocain. If these points are not adhered to the anesthesia is likely to be light and patchy. To allow sufficient time for anesthesia to develop, usually five to fifteen minutes is sufficient, but as long as thirty minutes may be required. This form of nerve blocking is free from danger, but the following objections have been raised against it: (1) The risk of injuring the subclavian artery. This should be avoided, as the artery can be distinctly felt. (2) The pleura may be injured, and the solution injected into the pleural cavity. (3) The possibility of paralysis of the nerve trunks of the arm arising as a result of the injection. Care should be taken not to inject the solution into a vein. To prevent this, the plexus should be sought for with the needle alone, when, if a vein is punctured, the blood will flow freely from the needle. Puncture of a vien, the authors maintain, produces no ill effect beyond a slight swelling in the neck.

**Gastric Juice Anaphylaxis.**—Manoiloff sums up the status of this subject up to the time of his own researches as follows: The gastric juice of cancer patients in which the localisation is not confined to the stomach (extra stomachal cancer) causes no toxic action when injected subdurally into guinea pigs—even is the amount of 1 c.c.; the gastric juice of patients with extra stomachal cancer when injected subdurally into animals previously treated with mammary cancer extract does not cause the phenomena of anaphylaxis; but the gastric juice of a patient with intrastomachal cancer when injected subdurally into healthy animals, even in doses of 0.05 c.c., causes a strong toxic action ending in death; and when this juice is injected subdurally into animals previously treated with extract of mammary cancer, even in the minimal amount of 0.2 c.c., distinct phenomena of anaphylaxis are produced. The author's work along the same line has shown him that gastric anaphylaxis in subjects with gastric cancer is a strictly specific phenomenon. In animals treated previously with cancer juice, the extract of gastric juice of patients with gastric cancer gives rise to anaphylactic phenomena, whereas if the gastric juice of patients with extrastomachal cancer is used, Manoiloff says no anaphylaxis results.

**Nature of Arthritis Deformans.**—This affection is widely distributed and has serious and fateful consequences, yet we know almost nothing of its nature, despite the fact that numerous specialists of medical practice are alike interested in its study—internists, surgeons, orthopedists, röntgenologists, etc. The cartilage degenerates up to complete loss; there is a usury of the cartilaginous surfaces, and the characteristic uneven contour of the joints are in evidence. An atrophic condition of the bone is accompanied by the formation of osteophytes which have a cartilaginous source. The atrophic bone changes are accompanied by sclerosis. What now is the final cause of all these changes? Histology furnishes the sole prospect of solution but so rapid and multiform are the changes that we are forced to seek for the very earliest alterations. None of the innumerable theories enunciated in the past are of any assistance in explaining the primary lesion, necrosis of cartilage; and all other phenomena may be regarded as reactionary. Much experimental work has shown the great likelihood of this possibility. Necroses of the joint cartilages may be produced in dogs by electrolysis; and the sequential phenomena are strictly parallel with those of arthritis deformans in man. Knowledge of the cause alone can give us hope of rational treatment. The causal factors may be multiple. Trauma and a mild degree of arthritis may alike produce the superficial ulceration; while the arthritis itself may be due to several causes—in one instance perhaps to circulatory disturbances causing hemorrhages, in another to the activity of bacterio toxins. Another factor is, however, absolutely needed as a predisponent and this is beginning senile involution. Weichselbaum goes so far as to state that arthritis deformans is merely an intensification of a physiologic process. To explain further the nature of the affection, especially in certain joints like the knees, a static element must be evoked. The amount of weight supported, the pressure and friction here may all contribute in the evolution of the affection and the best hope for treatment comes from a due regard to this element, which may also be a factor in the initial manifestations.

**Radiant Energy and Deepseated Cancer.**—Aschoff Krönig, and Gauss have tested the power of radium and *x*-rays upon the tissues of deep-seated cancer inoperable in nature. The action of the rays was verified by histological investigations. A few cases are given in great detail, of which number we may select one. The woman had an inoperable cancer of the cervix. The first trial excision revealed a noncornifying squamous epithelioma. Another excision was made during the radiation. Some difference was noted between the two specimens, the most recent showing much fewer mitoses. From then until patient's death many trial excisions were examined. It was evident that no essential alteration of cancerous tissues had been effected. At the last the cells were very large, simulating plant cells. The protoplasm was quite transparent. Here and there pronounced pearl formation was in evidence. The vessels were greatly thickened, with infiltration of their walls with leucocytes. Autopsy showed that the growth had spread in an ordinary fashion. The cancer involved uterus and vagina with perforation of the rectum. The left parametrium was infiltrated and the process had invaded the left tuber ischii. The growth had involved both ureters and had caused bilateral hydronephrosis. The pelvic veins were the seat of extensive thrombosis. Recent emboli were found in the lower lobe of the lung to the right, with secondary gangrene. Since the cases tested were condemned at the start, and since the autopsy finds showed no serious changes from the normal, the research is evidently not made in the interest of a prospective remedy but simply to secure and place on record certain data in reference to radiophysiology and radiopathology. The article will be continued.

**Appearance of Virulent Tubercle Bacilli in the Blood After the Diagnostic Tuberculin Injection.**—Bacmeister speaks of the extensive recent literature of this subject, due to the publication of the methods of Stäubli and Schnitter in 1908 and 1909 respectively. These processes enable the investigator to demonstrate acid-fast bacilli in smears from a few cubic centimeters of blood. This result, however, leads to surprising conclusions, quite out of harmony with what we knew before of the occurrence within the body of this bacillus. Not only may consumptives in the initial stages, but even seemingly healthy subjects have their blood swarming with the germs. But the latter give quite negative results in animal experiment, in contrast to those bacilli which accompany actual tuberculosis. The conclusion must naturally be this, that the avirulent germ, while seemingly identical with Koch's bacillus, is nevertheless distinct as to pathogenicity. We have, however, learned incidentally that among all these finds in the blood—and by intensive methods they are practically universally present—there are more cases of genuine tubercle bacillemia than had been supposed. Quite recently by persistent work Liebermeister found that when a tuberculous focus is actually present in the body, the genuine bacillus not infrequently is present in the circulating blood, as shown by its virulence to animals. In other words, the harmless bacilli may become activated in the presence of a focus. The author, however, often found avirulent bacilli in the blood when actual pulmonary lesions were present. It then occurred to the author to give these cases a diagnostic tuberculin injection, the pulmonary tuberculosis being of mild type. This was done in fifteen cases, and at the height of the reaction blood was taken and injected into the peritoneal cavity of rabbits. But of thirty cases (each patient tested twice) but four positive animal results were obtained. The bugbear that tuberculin necessarily expels virulent bacilli into the circulating blood should not therefore continue to prevail. The local focus may be unduly activated and may be made worse, but the fear of acute infectious bacillemia which dates from the discovery of the tuberculin reaction, and which may tend to reappear with the recent demonstrations by Staubli's method, is apparently unfounded. The present safeguards should be more than sufficient to prevent such catastrophes.

*February* 13, 1913.

**Abderhalden's Dialysis Procedure in the Explanation of Psychoses.**—This procedure, as Fauser states, which is intended for the demonstration of certain albumins in the blood which do not belong therein, notably the placental albumin of gravidæ, has been applied to certain psychoses believed to be due to some defective or uncorrected presence of organic matter from the ductless glands. The author has already published two papers on the subject and hence does not stop to describe his technique. His conclusions are as follows: In most cases of dementia præcox, and especially in the hebephrenic form, there is at fault a disturbance of the genital glands, in which also the thyroid sometimes participates. To some extent these disturbances are inborn, although the thyroid factor when present is perhaps acquired. The metabolic disturbances in these glands are not corrected outright with hormone production but lead to the formation of a protein mattér which is foreign to the blood, and hence requires the antagonism of the protective enzymes of that fluid, the resulting cleavage substances being responsible for the reaction. The same products, it is assumed, are able to act upon the cortex cerebri and induce perverted psychic functions. In this way other metabolic products are produced, so that a vicious circle results. Thus far the author has found no cleavage product of the ovary in men with dementia præcox, nor of the testicle in women. Again, as a fact of great significance, the genital glands of the elderly of both sexes are able to form these heterologous substances as well as those of young or middle-aged subjects. Aside from dementia præcox the subject of dementia paralytica comes into play in this connection. No doubt, in this affection there appear in the blood, as a direct result of the action of the syphilis virus, certain substances of whatever source which are comparable throughout with the toxic cleavage products of dementia præcox. The author is much strengthened in his belief as to the causes of dementia præcox already given, because he can find no evidence of a similar origin for manic-depressive insanity. In other words, dementia præcox and paralytic dementia are somehow related in being toxigenic, while other forms have not shown that origin.

**Development of the Adrenals.**—Landau sums up his study of this subject as follows: Human adrenals, in contrast with those of quadruped, showed a special richness in convolutions as well as a more marked development of the cortex about the great medullary veins. The human suprarenal organ, in contrast, shows a more marked growth in the first half of pregnancy, a deeper furrowing in the second half and a degeneration of the internal cortical portion after delivery. As these characteristics are not seen in lower animals, the condition represents a phylogenetic advance, such as is seen in one other organ only, the brain. Hence we can readily understand why in certain cerebral malformations (anencephali) we find hypoplasia of the adrenals. The richness in convolutions in the human adrenals shows further a marked analogy with the human cortex cerebri. This is seen not only on the exterior but also the internal surface of the adrenal cortex. We also behold here a certain definite relationship between the adrenal cortex and the sympathetic nervous system.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS

BY THE INSURANCE EDITOR.

### PRINCIPLES OF LIFE INSURANCE.

*The Interest Rate.*—The only sources of income for the payments due on policies by life insurance companies are the premiums and the interest earned on the premiums. It follows that in computing the premium, a certain rate of interest must be assumed and that this rate must be one which the safest possible securities may be depended upon to earn. The precise rate of interest to be earned cannot be determined in advance and as life insurance contracts usually run over a long period of years, the rate should not exceed three and one-half per cent. in the United States. Invested funds will surely earn a higher rate for many years to come, however, thus very properly assuring a margin of safety without which a life insurance company would be in a very poor position to promote a feeling of security among its policyholders. By assuming a higher rate and failing to heed the demand for safety, considerable doubt would exist as to whether all obligations could be carried out to the very end. Moreover, the gains and savings from the excess of interest earned over and above the three and one-half per cent. are applicable to dividends and will be returned to the policyholders in this form, especially in mutual and mixed companies.

Interest is therefore an important factor in the practice of life insurance and elaborate tables have been compiled to show at a glance, not merely what every dollar will earn at a given rate of interest in a certain number of years, but also how much must be invested at the present time so that in a certain number of years at a given rate of interest it will increase to a stated sum. Limited space forbids the insertion of these voluminous tables.

*Combination of Mortality and Interest Tables.*—The course of the hypothetical company referred to in the previous article may now be resumed. It was learned from the mortality table that of the 81,822 policyholders, composing the company and entering at the age of thirty-five, 812 members will die during the tenth year and that $812,000 will be required in that year to pay these death claims. On consulting the interest table, it is seen that the present worth of $812,000 is $575,626.80, that being the sum which will amount to $812,000 at three and one-half per cent. interest in ten years. Therefore, with $575,626.80 on hand in the beginning of the company, each and every one of the death claims in this group can be paid by the company. In the same way it is apparent from the mortality table that in this same company there will be 1,143 deaths in the twentieth year at the age of fifty-four, calling for the payment of $1,143,000, and the interest table shows that the present worth of this sum is $574,471.80, this being the amount which invested at three and a half per cent. for twenty years will create a fund just sufficient for the payment of the claims coming due in this group of policyholders. Another group of policyholders is made up of the three members who will live out the sixty-one years and attain the age of ninety-five, their deaths during that year calling for the payment of $3,000; the sum of $367.93 on hand in the beginning and invested for sixty-one years at the rate of three and a half per cent. will just pay in full the claims of the last three members of the company.

In a like manner, it can be computed from the mortality tables what the losses will be for each and every year during the course of the company for the sixty-one years, and the interest tables will determine the present worth of the amount which will be needed in each and every year. By working out this problem it will be found that the present worth of the $81,822,000, required as a total insurance fund for the payment of each and every claim is $30,319,142.10. With this amount on hand at the outset, the fund will be sufficient to meet every demand to the very end without the necessity of the addition of new members. Dividing $30,319,142.10 by 81,822, the original members of the company, gives $370.55. If each of these members, then, pays down $370.55 at the beginning of the first year of the company, there will be a total fund on hand just sufficient to fulfill all the contracts. This $370.55 is termed the *net single premium* and it is the net amount, without provision for expenses, which a man at age thirty-five should pay for a fully paid-up policy of $1,000. As most men find it inconvenient, however, to pay for their life insurance in a single sum, it is necessary to divide the net single premium into equivalent yearly payments to be made by the insured during life. The description of the mathematical process involved in this computation takes several other questions into consideration, and these will be discussed in the next article.

---

**Selection and Training of Medical Examiner.**—Dr. Edmund Babler says that in selecting examiners most companies simply get a list from some friendly company and then get the standing of the physician from a commercial report company. This is quite unsatisfactory and Dr. Babler has had a special inspector appointed to go about and get personal evidence as to the standing of the candidates. Usually two, or even three, examiners are appointed for one locality, and the agents are always urging the appointment of others. Little is done in training the examiner, for the usual book of instructions is inefficient and monthly instructions are not usually attended to by the examiner.

As a remedy for this Dr. Babler thought that a list of accredited examiners should be prepared for the American Life Convention by a special committee empowered to act by the members. Each company could then be supplied with a list of accredited men, and of men that have been "discontinued" or are undesirable.

The plan is ambitious and is altogether too expensive to be carried out by a single company but its advantages appear to the writer to be so great that an association of companies should find it profitable to adopt the scheme.

In the discussion, Dr. Spratling said that his company tried inspectors but has found that a medical man will not do the work for the salary offered while a layman somehow could never judge a doctor. The only way to get good examiners is to try out doctors and check up their work. Nothing but experience is good enough for selecting proper examiners. Dr. Spratling said that the agents have a voice in the appointment of examiners and he has come around to the idea that this is not a bad thing. —Proceedings of the Second Annual Meeting of the Medical Section of the American Life Convention.

# Book Reviews.

THE HISTORY OF THE PRISON PSYCHOSES. By PAUL NITSCHE of Dresden, and Karl Willmanns of Heidelberg. Authorized translation by FRANCIS M. BARNES, Jr., M.D., Senior Assistant Physician, Government Hospital for the Insane and Instructor in Neurology and Psychiatry in the George Washington University, Washington, D. C.; and BERNARD GLUECK, M.D., Senior Assistant Physician, Government Hospital for the Insane, Washington, D. C. With an Introduction by WILLIAM A. WHITE, M.D. Price $1.25. New York: The Journal of Nervous and Mental Disease Publishing Company, 1912.

"THE study of the insane criminal," says Dr. White in his Introduction to this interesting little volume, "is one of the best approaches to an understanding of him, as a study of the psychology of mental disease is one of the best methods of approach to the understanding of the normal individual." In line with such a study is this historical review of the prison psychoses and their development, from the time of the pioneer publication of Delbrück, physician to the penal institution at Halle, in 1853, to the present day. The work is confined to the German literature on the subject. There are two general types of criminal psychoses. One comprises cases of mental disorder in criminals, which are termed "accidental" in occurrence, which present no especially new problems and which are easily classified in classifications utilized for the non-criminal insane. The other general type includes certain psychoses which seem to be found only among the confined criminal insane. Individuals developing this latter type exhibit a peculiar mental make-up and many of them have a peculiar symptom complex which makes it very difficult, or practically impossible of classification with psychoses in non-criminals. This complex is of psychogenetic origin and reactive to certain specific unfavorable environmental conditions. It is to this latter class that the term "prison psychosis" peculiarly applies; and, as stated in the translator's preface, "from the practical side, the term certainly is of value in that it emphasizes the etiologic potential of imprisonment as a provocative agent in the causation of outspoken psychotic states which properly demand hospital care." More intelligent methods of dealing with the criminal and with all the problems of criminology are very much needed. If it is true that the average criminal is of a low type of intelligence, often lacking in attention, imagination, and ability even to use what little intellect he has, can we best help in the problem by punishment alone? We recommend this work of Nitsche and Willmanns to help us answer the question. The first part of the book embraces the works of the old school. The second considers the question of prison psychoses from the standpoint of Kraepelin's conception of dementia precox. The third and last part is a review of the subject from the standpoint of the Magnan-Möbius ideas on degeneracy.

FOR AND AGAINST EXPERIMENTS ON ANIMALS. Evidence Before the Royal Commission on Vivisection. By STEPHEN PAGET, F.R.C.S., Hon. Secretary Research Defence Society, With an Introduction by THE RIGHT HON. THE EARL OF CROMER, O.M., G.C.M.G., G.C.B. Price $1.50. New York: Paul B. Hoeber, 1912.

THIS publication is both timely and useful. It gives a clear account of the results obtained during the past thirty years by the help of experiments on animals; and in many instances the account is given in the very words of the men who did the work. Not the least interesting part of the book is the Anti-vivisection evidence; Mr. Coleridge's own admission that he himself cannot be depended on to speak the truth (unless it happens to suit his own convenience) is something to be remembered. The volume makes interesting and instructive reading; physicians and surgeons should have the book, and lend it to patients, or leave it on the table of the waiting room.

SELECTED PAPERS ON HYSTERIA AND OTHER PSYCHONEUROSES. By SIGMUND FREUD, Vienna. (Second, Enlarged Edition.) Authorized Translation by A. A. BRILL, M.D., Ph.B., Chief of Nervous Department, Bronx Hospital and Dispensary; Clinical Assistant, Department of Neurology and Psychiatry, Columbia University. $2.50. New York: The Journal of Nervous and Mental Disease Publishing Company, 1912.

THE first edition of this work appeared only three years ago at a time when there was scarcely anything available of Freud's writings translated into English. Those who had tried to read Freud in the original immediately appreciated the convenience and saving of time of the translation and the first edition was soon exhausted. It is needless to review the book again in the MEDICAL RECORD except to say that the "Papers" are taken, for the most part, from the *Studien über Hysterie*," published by Breuer and Freud in 1895, and from Freud's "Sammlung kleiner Schriften zur Neurosenlehre," Vol. 1, 1906, and Vol. 2, 1909. The present edition shows some revision, and it has been enlarged by the addition of a chapter "On Wild Psychoanalysis" and a chapter on "The Future Chances of Psychoanalytic Therapy." The first of these added chapters was apparently needed, to restrain the overzealous blind partisan. The second is calculated to make new converts to psychoanalytic therapy by the author's fine philosophic treatment of the general problems of the subject and the insight he gives us into newer fields of investigation. Let us not condemn the Freudian principles until we at least have read them and tried to understand them. In order to do this more of his writings than those comprised in this book will have to be carefully studied and put into practice; but the Selected Papers on Hysteria are excellent to begin on.

THERAPEUTICS, MATERIA MEDICA, AND PHARMACY, Including the Special Therapeutics of Diseases and Symptoms, the Physiological and Therapeutic Actions of Drugs, the Modern Materia Medica, Official and Practical Pharmacy, Minute Directions for Prescription Writing, also the Antidotal and Antagonistic Treatment of Poisoning. By SAMUEL O. L. POTTER, A.M., M.D., M.R.C.P. Lond. Formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco; Author of the "Quiz-compends of Anatomy and Materia Medica," "An Index of Comparative Therapeutics," several articles in Foster's "Practical Therapeutics," and "Speech and Its Defects"; late Major and Surgeon of Volunteers, U. S. Army. Twelfth Edition, revised and enlarged. Price $5.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

THIS is probably one of the best known and most widely used works on Therapeutics and Materia Medica in the English language; and since it is now in its twelfth edition it certainly needs neither commendation nor introduction. The author keeps his book well up to date, and at the same time shows no little skill in preventing the volume from reaching unwieldy proportions. The present edition is only eighteen pages larger than before, and contains new articles on: Acidum Nitrosum, Alypin, Arteriosclerosis, Arsenobenzol, Aspirin, Chromic Sulphate, Digitalone and other preparations of Digitalis, Enesol, Eugenol-acetamide, Fibrolysin, Guaiacose, Hydrargyrum Succinimide, Lactobacilline, Laxaphen, Edematous Laryngitis, Libradol, Medinal, Novaspirin, Novocaine, Pellagra, Pertussin, Phenolphthalein, Sodium Nucleinate, Trypsogen, Uriform, Valyl, and Veracolate. The section on Serums and Vaccines has been rewritten and enlarged, and some obsolete material has been omitted. We know of no similar volume on Therapeutics and Materia Medica containing anything like the same amount of valuable information.

PLATISCHE OPERATIONEN (Plastic operations). By Prof. Ph. BOCKENHEIMER. Vol. I. With 258 illustrations, several in color. Price 9 Marks. Würzburg: Curt Kabitsch, 1912.

THIS work, which is to be completed in two volumes, is intended to present the progress and improvements which have been made in the domain of plastic surgery in the last few decades. The first volume, which has already appeared, contains a general section devoted to the principles developed in both the old and new methods and a special part dealing with the plastic operations which are applicable to the face. The author has freely referred to the clinical material observed in von Bergmann's service and also in private practice, together with numerous references to textbooks and journal articles. In the second volume, which has not yet appeared, the intention is to discuss the plastic operations employed in the remaining portions of the body. The perusal of the book makes it quite evident that its author has expended a great deal of time and thought in collecting from scattered sources the facts which may be included in the development of this branch of surgery. The writer discusses the indications and technique of the individual operations, but has very little to say regarding the subsequent results. Of particular interest is the section devoted to the correction of harelip and cleft palate, in which the author gives due recognition to the excellent work done by Brophie of Chicago, although he is not ready to admit that the method is more advantageous than others which have been proposed. The book is very well printed and satisfactorily illustrated with a large number of cuts and also several colored plates taken from the same author's well known atlas of clinical surgical pictures.

Gynäkologisches vademekum für Studierende und Ärzte. (Manual of Gynecology for Students and Practitioners.) By Prof. A. Dührssen, Berlin. With 138 illustrations and 11 plates. Tenth edition, enlarged and revised. Berlin: 1913, S. Karger.

The ten editions of this little book have succeeded each other very rapidly and the final one contains a number of additions which bring it up to date. In the ninth edition of this work considerable new material was already included, among which were chapters on special methods of treatment before and after major operations, laboratory examination methods, and legal responsibility of the operator. Advances in anesthetic methods were likewise referred to. The question of early rising after operation is given very little attention by the author because his adherence to vaginal methods obviates in his mind this difficulty. The book in its 300 closely printed pages contains a vast wealth of material which, however, seems somewhat confusing to a beginner, as in many instances a method is described in such a brief manner that it can be of little value. An American reader will also be more or less astounded by the frequent references in the book to the proprietary preparations, which, aside from the ethics of the case, would not under ordinary circumstances be accessible to other than German readers.

Ophthalmic Surgery. A Handbook of the Surgical Operations on the Eyeball and Its Appendages as Practised at the Clinic of Hofrat Professor Fuchs by Dr. Josef Meller, Privatdocent and First Assistant K.K.II., University Eye Clinic, Vienna. Edited by Dr. William M. Sweet, Clinical Professor of Ophthalmology, Jefferson Medical College; Professor of Diseases of the Eye, Philadelphia Polyclinic; Attending Surgeon, Wills' Eye Hospital, Philadelphia. With 173 Original Illustrations. Second Edition, thoroughly revised. Price, $3.50 net. Philadelphia: P. Blakiston's Son Company, 1912.

The second edition of Meller's work is larger by about twenty pages than the first. "The text of the volume has been entirely rewritten and the subject-matter rearranged." New operations and new illustrations have been added. The work is not a complete treatise on the surgery of the eye, but is designed to describe the most important operations that are performed at the clinic of Professor Fuchs in Vienna, particularly those which have been adopted after large experience. The surgery of the lacrymal apparatus is given *in extenso,* particularly in regard to the excision of the sac, the operation for which, as advocated by Meller, is probably the best now practised. The directions for the extraction of cataract will not appeal to the up-to-date American ophthalmologist, as the position of the operator (sitting at the right side of the patient) does not correspond with the custom practised here (standing or sitting at the head of the patient, and some of the other steps advised are not in accordance with the most advanced views. All operations are fully and well illustrated and described. Because of the special features, if for no other reason, Meller's work should be consulted by all ophthalmic surgeons.

The Prognosis and Treatment of Diseases of the Heart. By R. O. Moon, M.A., M.O. Oxon., F.R.C.P., Physician to the National Hospital for Diseases of the Heart; Assistant Physician to the Royal Waterloo Hospital. Price, $1.25. London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1912.

This book is of an eminently practical nature, dealing almost exclusively, as proclaimed in its title, with the subjects of prognosis and treatment, although here and there a necessary word is said regarding etiology and diagnosis. Owing to this limitation of discussion it has been possible to compress a great deal of material of value to the young practitioner in a little over 110 pages of text. Dr. Moon is, of course, of the modern school of cardiologists who have learned to look upon certain diseases of the heart with less dread than formerly, or rather have learned to discriminate more accurately between the heart disease that kills and that which merely sounds a note of warning or at most slightly cripples. His therapeutic teachings are sound, and the general tenor of his prognostic notes is hopeful. The book is well worth reading and may give even the expert some new ideas or helpful hints.

Der Haftapparat der Weiblichen Genitalien. Eine Anatomische Studie. Von Dr. Eduard Martin, Privatdozent und Assistant an der Univfrauenklinik zu Berlin. II. Teil. Der prolaps. Mit 24 Tafeln. Berlin: 1912. Verlag von S. Karger.

The anatomical and clinical investigations which were described in the first portion of this work show that there may be distinguished in the female pelvis, two sets of structures, one consisting of fascial thickenings in the connective tissue, which are intended as a means of attachment, and another set which forms the pelvic floor and are intended for support. It was further shown that it is only the fascia or fascial thickenings in both sets of structures, and not the muscles which serve a physiological purpose. Along these lines the author has described a series of preparations of the pelvic contents and divided the various forms of genital prolapse on a topographical basis. According to this scheme the primary injuries to the structures that serve for attachment result in prolapse of the uterine bladder, hernia of the vesicouterine fold, prolapse and anterior displacement of the uterus, and hernia of the rectouterine fold. Primary damage to the suspensory apparatus results in a prolapse of the posterior vaginal wall, elongation of the cervix and secondarily to the deformities already noted. The final form of displacement is that brought about by a rectocele. Martin bases his description of these lesions on a series of anatomical preparations and clinical observations, which are illustrated by drawings and plates, and in each instance the appropriate therapeutic procedure is outlined. The work represents in a very graphic manner the entire domain of the reparative surgery of this section of the body, based on the advances in literature and also on the author's extensive personal experience in gynecological surgery.

Die Behandlung der Knochen- und Gelenktuberkulose mit orthopädischen Massnahmen. Von Dr. F. Oehlecker, chirurgischen Sekundärarzte. Sonderabdruck aus den Tuberkulose-Fortbildungskursen des Allgemeinen Krankenhauses Hamburg-Eppendorf. Band I. Price, 3 marks. Würzburg: Verlag von Curt Kabitzsch, 1913.

This little book of 90 pages, dealing as it does with the pathology, symptomatology, differential diagnosis, etc., of bone and joint tuberculosis, is somewhat broader in its scope than its title implies. Its author shows his familiarity with the best German authorities, and illuminates his text with illustrations of diseased joints, plaster-of-Paris dressings and a few braces. While the book might appear somewhat old-fashioned in its viewpoint, it is fully up to the standard set by many of its author's compatriots, and will doubtless be helpful to his fellow practitioners in their treatment of this most interesting class of diseases. In contradistinction to Stiles of Edinburgh, Oehlecker found that the bovine type of tubercle bacillus played a comparatively insignificant rôle as a causative agent in bone and joint tuberculosis. Out of 34 cases (28 children and 8 adults) only one, in a child, was due to the bovine type.

Hypnosis and Suggestion. Their Nature, Action, Importance, and Position Amongst Therapeutic Agents. By W. Hilger, M.D. (of Magdeburg). Translated by R. W. Felkin, M.D., F.R.S.E. With an Introduction by Dr. Van Renterghem (Amsterdam). Translated by A. Newbold. Price, $2.50 net. New York: Rebman Company, 1912.

This work has been translated into Dutch as well as English. The author is a general practitioner. He was a pupil of Torel and Vogt in 1895, and has utilized hypnosis and suggestive treatment more especially since that time. The book presents in an entertaining manner the essentials of the psychical curative methods and their application, as found in the author's own experience. The introduction by Dr. Van Renterghem contains a brief survey of the history of psychotherapy since 1843. At the present time, hypnosis has been largely superseded by other methods of psychotherapy. The author probably had that idea in mind when he produced this book. As a general practitioner, himself, he writes without apparent prejudice and does not omit to note the importance of instructive and explanatory treatment and re-education. But his main effort is apparently to spread a better understanding of hypnosis and suggestion, so that they may be more generally employed. There are four parts or chapters to the book. The first is devoted to a discussion of the nature and methods of hypnosis and suggestion. The second deals with suggestion and will. The third is on the influence of the will's action, suggestion, and various psychological factors in the disturbance of the area of sensation. And the last part describes the various disturbances of reflex activity and their treatment. A number of illustrative cases distributed throughout the book add to its practical interest. This book is one of the most conservative of the numerous works on the same subject. It may be of greater value to the general practitioner and to the layman than to the specialist, but it serves a good purpose and deserves to be read.

## MEDICAL LIBRARIES.*

### IV.

### 1913.

ALBANY.—New York State Medical Library. Albany, New York, U. S. A. Miss Ada Bunnell. 18,000.

AMSTERDAM.—Library of the Netherlands Medical Society. Singel 21, in the University Library. Dr. C. E. Daniëls. 25,665.

ANTWERP.—Library of the Antwerp Medical Society. Royal Atheneum, 40 rue van Straalen, Antwerp, Belgium. Dr. Edward d'Haenens. 3,150 (1911).

ATLANTA.—Library of the Atlanta Medical Association. Atlanta, Georgia, U. S. A. Dr. H. F. Harris. 2,000 (1911).

BALTIMORE.—Library of the College of Physicians and Surgeons. Baltimore, Maryland, U. S. A. Miss Ethel I. Disney. 1,275 (1911).

Johns Hopkins Hospital Library. North Broadway, Baltimore, Md., U. S. A. Miss Minnie W. Blogg. 12,000.

The Johns Hopkins Medical School Library. Baltimore, Md., U. S. A. Dr. M. L. Raney. 11,600.

Library of the Medical and Chirurgical Faculty of Maryland. 1211 Cathedral street, Baltimore, Md., U. S. A. Miss Marcia C. Noyes. 20,000.

Library of the University of Maryland, Faculty of Physic. Greene and Lombard streets, Baltimore, Md., U. S. A. Dr. Eugene Fauntleroy Cordell. 11,000.

BEIRUT.—Medical Library of the Syrian Protestant College. Beirût, Syria. H. Porter. 1,800.

BELFAST.—Library of the Ulster Medical Society. College Square, N. Belfast, Ireland. Dr. Wm. L. Storey. 2,000.

BERLIN.—Library of the Berlin Medical Society. Ziegelstrasse 10-11 (Langenbeck Haus), Berlin, N., 24, Germany. Dr. Hans Kohn. 40,000.

Library of the German Surgical Society. Ziegelstrasse 10-11, (Langenbeck Haus), Berlin, N., 24, Germany. Dr. Herman Fischer. 40,000.

Library of the Kaiser Wilhelm Academy. Scharnhorststrasse, 35, Berlin, N. W., Germany. Dr. A. Hiller. 67,000 (1911).

Library of the Imperial Public Health Department. 23 Klopstockstrasse, Berlin, N. W., Germany. Dr. Wurzburg. 70,000.

Library of the Society of Internal Medicine. Ziegelstrasse 10-11, Berlin, N., 24, Berlin, Germany. Dr. Max Meyer. 10,000.

BIRMINGHAM.—Library of the Birmingham Medical Institute. Edmund street, Birmingham, England. Mr. Thomas George Johnson. 14,928.

BOSTON.—Boston Medical Library. 8 Fenway, Boston, Massachusetts, U. S. A. Dr. John W. Farlow. 74,328.

Boston City Hospital Medical Library. 818 Harrison avenue, Boston, Mass., U. S. A. Dr. John H. McCollom. 3,000.

Library of the Harvard Medical School. Longwood avenue, Boston, Mass., U. S. A. Sarah Ripley Bartlett. 19,000.

Treadwell Library, Massachusetts General Hospital. Boston, Mass., U. S. A. Mrs. Grace W. Myers. 7,833.

Library of Tufts College Medical School. 416 Huntington avenue, Boston, Mass., U. S. A. Dr. Robert W. Hastings. 1,800 (1911).

Boston University Medical Library. 80 East Concord street, Boston, Mass., U. S. A. Dr. Anna T. Lovering. 5,347.

BRIGHTON.—Library of the Brighton and Sussex Medico-Chirurgical Society. Brighthelmstone Dispensary, Queen's Road, Brighton, England. Miss Evelyn Brill. 4,000.

BRISTOL.—Bristol Medical Library. University of Bristol, Bristol, England. Mr. C. King Rudge. 21,000.

BROOKLYN.—Library of the Medical Society of the County of Kings. 1313 Bedford Avenue, Brooklyn, New York, U. S. A. Mr. Albert T. Huntington. 65,000.

BRUNSWICK.—Library of the Medical School of Maine. Brunswick, Maine, U. S. A. Mr. George T. Little. 5,000.

BRUSSELS.—Library of the Royal Academy of Medicine of Belgium. Palais des Académies, Rue Ducale, Brussels, Belgium. Mr. Henri Beckers. 100,000.

*The name of the library is followed by its mail address, the name of the librarian, and the number of bound volumes. With the exceptions indicated this list is made up from recent returns up to January 15, 1913. Historical and economic details, degrees, and official titles are omitted. Copies may be obtained from the librarian of the New York Academy of Medicine.

BUDAPEST.—Library of the Royal Medical Society of Budapest. VIII Szentkiraly-utcza 21, Budapest, Hungary. Dr. Rudolphe Temesváry. 18,661.

BUFFALO.—University of Buffalo Medical Library. 24 High street, Buffalo, New York, U. S. A. Dr. Irving P. Lyon. 9,323.

BURLINGTON.—Medical Library of the University of Vermont, Burlington, Vermont, U. S. A. Dr. T. S. Brown. 2,000.

CALCUTTA.—Library of the Medical College of Bengal. Bowbazar, Calcutta, India. Ram Chandra Mookerjee. 50,000.

CHELTENHAM.—Cheltenham Medical Library. Clarence street, Cheltenham, England. Dr. J. Rupert Collins. 2,390.

CHICAGO.—Department of the Medical Sciences of The John Crerer Library, 87 Wabash avenue, Chicago, Illinois, U. S. A. Dr. A. C. Girard. 53,000 (1911).

Library of Northwestern University Medical School. 2431 Dearborn street, Chicago, Ill., U. S. A. Dr. Walter H. Buhlig. 6,518.

Quine Library, College of Physicians and Surgeons, Congress and Honore streets, Chicago, Ill., U. S. A. Miss Metta M. Loomis. 13,896.

Rush Medical College Library. Chicago, Ill., U. S. A. Miss C. A. MacAuliff. 19,522.

CINCINNATI.—Library of the Academy of Medicine of Cincinnati. 25 East Eighth street, Cincinnati, Ohio, U. S. A. Dr. Arch I. Carson. 3,000 (1911).

Cincinnati Hospital Library. Cincinnati, O., U. S. A. Dr. E. W. Mitchell. 18,958.

CLEVELAND.—Library of the Medical Library Association. 2318 Prospect avenue, Cleveland, O., U. S. A. Mrs. S. M. Harding. 17,000 (1911).

COLORADO SPRINGS.—El Paso County Medical Society Library. Coburn Library, Colorado Springs, Colorado, U. S. A. Mr. M. D. Ormes. 3,000.

COPENHAGEN.—Library of the Copenhagen Medical Society. Vester Boúlevard, 6, Copenhagen, Denmark. Dr. Jocrgen Moeller. 8,193.

Library of the General Hospital. Kommunehospitalet, Copenhagen, Denmark. Dr. Joergen Moeller. 4,830.

DANBURY.—Wile Medical Library. Danbury Hospital, Danbury, Connecticut, U. S. A. Mr. M. L. Rogers. 926.

DENVER.—Library of the Medical Society of the City and County of Denver. 266 Metropolitan Building, Denver, Colorado, U. S. A. Dr. A. J. Markley. 7,325.

DUBLIN.—Library of the Royal College of Physicians of Ireland. Kildare street, Dublin, Ireland. Mr. Robert Phelps. 15,500.

Library of the Royal College of Surgeons in Ireland. Stephens Green, Dublin, Ireland. Alfred Miller. 33,000.

EDINBURGH.—Library of the Royal Medical Society. Melbourne place, Edinburgh, Scotland. Mr. A. P. Ormiston. 30,000.

Library of the Royal College of Physicians of Edinburgh. 9 Queen street, Edinburgh, Scotland. Thomas Harkness Graham. 100,000.

Library of the Royal College of Surgeons of Edinburgh. Nicolson street, Edinburgh, Scotland. Mr. Harold J. Stiles. 16,000.

FALL RIVER.—Fall River Medical Library. 109 South Main street, Fall River, Massachusetts, U. S. A. Dr. George L. Richards. 1,200.

**Parallelism Between Gout and Diabetes.**—G. Guelpa believes that both of these disorders are of common origin but widely separated in their later development, symptomatology, and treatment. They both result from an excessive diet, which exaggerates the functional activity of the metabolic organs and causes an increase in the ordinary urinary constituents. There then occurs a condition of metabolic fatigue. At this stage diabetes and gout diverge in their manifestations. In the case of the former there occurs an accumulation of soluble acids in the blood including β-oxybutyric acid, diacetic acid, and other acids less well known; and in the case of the latter disease there is a deposition of an excess of uratic and calcareous constituents of the blood.—*Bulletin et Mémoires de la Société de Médecine de Paris.*

# Society Reports.

## PRACTITIONERS' SOCIETY OF NEW YORK.

*Two Hundred and Fifty-Second Regular Meeting, Held January 3, 1913.*

THE PRESIDENT, DR. BRANNAN, IN THE CHAIR.

**Beatson's Operation for Recurrent Mammary Carcinoma.**—Dr. ABBE presented two patients illustrating the remarkable effects of oophorectomy on inoperable recurrent mammary cancer. One was a young woman, who a year and a half after operation appeared in excellent health, but who showed the early secondary recurrence after the usual effect of Beatson's operation declined. But the case suggests the thought of possible other benefits that might carry on the beneficent action. He had shown the patient to this society fourteen months ago, just six months after operation for removal of the ovaries. Her condition then was absolutely free from any visible or palpable evidence of disease, and she was in admirable health and working heartily, whereas at the time of the operation she had had a mass of solid recurrence around the scar of the original breast operation which could scarcely be covered by the hand—a veritable cuirass carcinoma. Besides this there were supra- and infraclavicular nodes on both sides and a new cancer mass on the unoperated side as large as a small pullet's egg, with axillary nodes; also one cutaneous metastatic node in the skin over the shoulder blade. Every vestige of these growths melted away and left the patient seemingly in restored health. In one of her ovaries was found a metastatic cancer the size of a pea. One month after exhibition to this society a half dozen shot-like nodes were discovered near the old scar. These disappeared rapidly under radium influence. During the past year numerous others, always of small size, had come and had been dissipated. Of late they were not yielding so well, yet the patient was in excellent health and full weight. It had now occurred to him to try the effect of serum injections, of rabbit's serum from a rabbit whose ovaries were removed two weeks before. Three injections of twelve c.c. of fresh centrifuged serum had been given one week apart. It was too early to see the effect, but the experiment seemed worth making, inasmuch as the inhibitory action of her own serum, freed from her own ovarian secretion, might possibly be continued by using that of another animal. A later report would be made; meanwhile radium was sufficient.

The second patient exhibited an enormous generalized recurrent carcinoma with extensive and very active ulceration in the cicatricial mass. About one hundred and twenty independent metastatic nodes had been counted; none smaller than the end of the finger, scattered over the front of the chest and inoperated breast, from the clavicle to the epigastrium, and beyond the carcinoma cuirass in the operated field far around the axilla to the scapula. Four weeks ago her ovaries had been removed, each presenting a cancer node. The effect on the generalized carcinomas had begun in one week and progressed steadily to present improvement. The ulcerated mass had become pale and was cicatrizing rapidly; the nodules were everywhere flattening and umbilicating. There was little doubt that she also could be shown to the society after a few months free from apparent disease. He designed not only to exhibit types of this unique surgical state, but to stimulate study of the biochemistry of the ovarian secretion, as well as to demonstrate that we might yet find in Beatson's operation, combined with radium, which was a valuable supplemental resource, a means of extending our hopes and aid.

Dr. BRYANT asked whether in case of cancer that seemed to be more or less scattered through the tissues, it would not be important to associate radium therapy with operative procedure; whether the disease returned at the situation where the radium caused its disappearance; whether new growths appeared when the radium had ceased, and whether new growths occurred between the places where radium had dispelled other growths.

Dr. CONNER said that the striking effects of removal of the ovaries upon malignant growths raised many interesting points. It would seem as though such effects must depend upon the general nutritive changes which resulted from removal of the sexual glands, and it suggested that others of the glands of internal secretion, such as the hypophysis, might have equally important influences upon such growths, which might ultimately be utilized in the treatment of these conditions.

Dr. Abbe said that he had been interested twelve years ago in oophorectomy for recurrent mammary cancers and had operated on ten cases. He had given it up for a while, but his interest in it had been revived. He found that when the beneficial disappearance of recurrent masses following oophorectomy began to wane, and small recurrences to begin, radium then exerted its beneficial action and prolonged the immunity. The influence of radium tended to become exhausted; it became too painful in time to be used, although at first it allayed pain as an anodyne. He hoped, however, that in time some other agents would prove available to take up the cure where radium was no longer of service. The effect of radium was local and for a certain depth only. The possibility of a serum treatment might here be of use. If the removal of the ovaries in the patient so far altered metabolism as to cause a disappearance of the growth, the serum of some animal from which the ovaries had been removed might produce a similar effect. He had lately made an experiment with rabbit serum from an animal with removed ovaries, using 12 c.c. of the serum for injection. In some apparently hopeless cases the serum treatment might prove of use. He was trying this.

Dr. Cleveland said he had had no experience with Beatson's operation, but he wished to say that it seemed to him that the operation itself had an effect upon the development of the disease, and that, if the radium could be used as a supplementary treatment to check further growth, there was distinct reason for encouragement.

Dr. Abbe presented patients illustrating the paper of the evening. Some had undergone hemiglossectomy for epithelial carcinoma. He asked one man, a lawyer, to speak and show the effect of the operation. The patient said that he had very little difficulty in speaking if he spoke slowly, and that only a few words were any trouble to him. He was able to speak in court and pursue his calling. Case 2 was that of woman who had had a cancer of the inside of the cheek, the gum, and part of the tongue, necessitating partial glossectomy and removal of the half cheek and jaw. The woman had been in perfect health for five years since the operation and experienced no discomfort and was not greatly disfigured.

Cases of leucoplakia were then presented, showing typical white patches, or "smoker's patches." One unusual case occurred in the cheek, where the quid of tobacco was held. These cases had responded to radium when nothing else would effect a cure. A case of epithelioma of the lip was shown of a kind that usually required surgical interference. This was successfully treated with radium and remained cured after two years. In a case of lymphangiectasis, where the entire left side of the tongue had been a bleeding mass, radium treatment had reduced it by half. The condition had been brought down to a flat surface and papillary tissue. A patient was also shown who had had a large giant-celled sarcoma of the jaw which had been treated by radium and had disappeared for eight years and had not recurred. This had occupied the entire bone of the jaw. The teeth were loose but were now solid. The bone had been almost entirely absorbed, but there was now a perfectly solid bone.

Dr. Abbe brought for inspection many colored casts, to show the conditions in various malignant diseases of the jaw and mouth.

**Malignant Disease of the Mouth and Tongue.**—Dr. Robert Abbe read this paper. (See page 461.)

Dr. Bryant congratulated Dr. Abbe and the members of the society on the artistic feature introduced by the casts and the amount of information they gave to those who saw them. If all surgeons made such diligent observations and collections it would be of immense advantage and would indeed add much to the history of surgical attainment. Speaking of giant-celled sarcoma, he said he had come across many of these cases, but he had never considered radium a necessary method of cure. He did not consider the giant celled sarcoma a malignant manifestation. He had treated at Bellevue several cases by free removal, and without return, of the growth. He felt it pretty hopeless to attack a cancerous condition of the mouth and tongue, especially if well advanced in nodular infection, except for the purpose of giving physical or mental relief. The idea that something was being done and the relief of the removal of the disease from the mouth cavity gave comfort and help to the patient. Very often a patient with a malignant disease which had been pronounced hopeless died of something quite different. The disease itself was modified largely by the stamina of the patient, his habits, etc. Very often extensive disease might occur without manifestations. A patient had come to him with a short-standing severe pain in the ear; he had found the pharynx was involved in an extensive cancerous process on the painful side, yet the patient was positive that the pain was the first indication he had had that he was afflicted with the disease.

Dr. Ewing said that he had been greatly impressed with the results of Dr. Abbe's work but that it was clear to him that these results were very largely due to Dr. Abbe's special knowledge of radium. Wickham and de Grais also accomplished results that no one else could get. It would be valuable if more attention could be paid to the methods of applying radium. Some investigators who worked with radium accomplished nothing. They probably attempted too much. Most observers acknowledged defects in controlling the dosage. This matter of want of experience in dosage stood in the way of the general application of radium. Additional guidance might be had if more were known of the histological characters of the cases treated. Papillomas of the tongue were very different processes from infiltrating carcinomas. The various types of sarcomas also would bear careful subdivision. Wickham and de Grais had cured mixed tumors of the parotid with radium. These were somewhat difficult to handle surgically. It seemed probable that careful study might reveal certain other specific diseases in which radium would give excellent therapeutic results. He said that changes from a wart to carcinoma were frequent in the bladder and larynx but were very infrequent on the tongue and lip.

Dr. Flexner said he would like to refer to one point brought up by Dr. Abbe's paper, namely the influence of injury to cells in promoting the development of tumors. At the Rockefeller Institute, Dr. Rous had now obtained, from three chicken tumors, Berkefeld filtrates that were capable of causing similar tumors to develop upon inoculation into healthy fowl. One of the tumors produced bone and cartilage. When these filtrates were injected into the breast muscle, a tumor developed at the site of inoculation and not elsewhere, and for the reason that the introduction of the needle produced an injury at that point. When, however, there was suspended in the filtrates some infusorial earth, containing the skeletons of diatoms, which were capable of penetrating and injuring the cells, the filtrates were then capable of setting up tumors in the various internal organs to which the diatoms were carried. The demonstration, therefore, was in this series of instances conclusive that these growths, which were of malignant character, required, as a condition of their development in the body, injury to the normal cells, which otherwise seemed able to resist the action of the causative agent.

Dr. Taylor said that in a case of leucoplakia of the tongue removed by dissection the wound healed by primary union, but the woman returned 5 years later with a well developed carcinoma in the scar of the old operation.

Dr. Kinnicutt said he knew a case of a man who at 75 years had an exaggerated form of leucoplakia, the whole tongue being covered. He had had this 15 years when he died from another cause, but he had no evidence of epithelioma.

Dr. Wood said that such work as Dr. Abbe had reported was of great value to the pathologist for it furnished him with information not obtainable in other ways. Malignancy was a clinical phenomenon, and there was no real criterion of malignancy under the microscope. All we knew was that tumors of a certain morphology recurred and that others of a different morphology as a rule did not recur after removal. Dr. Abbe had shown that an epulis or giant celled sarcoma was influenced by radium, a proof of the relatively benign nature of these growths, which because of their morphology must be called sarcomata. The results presented tallied with the work of Bloodgood in Baltimore, and with a recent German summary in which, of seventy-two cases of giant celled sarcoma of the gum, only two recurred after excision.

Dr. Gibson said it was very interesting if leucoplakia could be cured and so prevent cases of carcinoma. If radium could affect superficial growth it was sometimes a better mode than a surgical one. Malignant growth might recur any time, twenty or thirty years after, and radium apparently was of no value in deep seated growths.

Dr. Brannan asked if Dr. Abbe could teach his house staff to keep such records, and if it were possible to direct radium so that it could be used for internal tumors.

Dr. Thacher asked if there had been any recurrence in any of these cases.

Dr. Abbe said in reply to Dr. Thacher that there had been frequent recurrences because of insufficient dosage of radium in many cases. The giant-celled type of growth yielded more readily than the mixed spindle-celled and

fibrous types. Replying to Dr. Brannan he said he had done this work mostly himself with a sense of duty and it had materially helped him. He found it difficult to educate his house officers to do it. He said that in primary cancer of the liver and renal sarcomas he had placed radium tubes within the growth with valuable results, but not as yet permanent benefit. It was all on trial. He said he was sorry to note an erroneous impression that he had made claims for radium that he had not intended. His design had been to show that radium could do what other resources could not do. Radium fell short of doing what we should like to have it do. Surgery, first, last, and all the time, was still our greatest resort. Radium had wrought little as yet in internal cancer, and nothing had been claimed for it. The study led to interesting ideas. Dr. Ewing had spoken of parotid tumors. He had treated one case of a large parotid tumor which almost disappeared; about four years later it had started to grow again, but with treatment it was kept down and never became as large as at first. He had seen large parotid tumors, almost hopeless cases, which yielded favorably to radium. Sarcoma of the jaw might well be called malignant when one inch of the jaw was destroyed. Radium made solid bone again in such cases. There was under his care one old lady 75 years of age who had had a distressing bleeding mass of tumor entirely disrupting the right lower jaw. Radium was kept for six hours in the center of the mass, which soon began to shrink, and in time the bone became perfectly solid. This case duplicated the remarkable one shown the society to-night, eight years after perfect restoration through radium. This could not have been accomplished through surgery. In cases of involvement of the gums when the growth appeared between the teeth, either epithelioma or giant celled sarcoma, the tumor had disappeared with treatment and the teeth had been retained. Surgeons would have taken the teeth out and sacrificed the surrounding bone, but surgery could not induce ossification in the tumor which radium could do. He did not wish to be considered as exploiting radium, but it did things which surgery could not do. In time it might be hoped that a unit of effect could be reached and radium treatment could be more regulated. In Germany it was used by injections.

**Case of Cerebral Tumor Cured by Operation.**—Dr. Dana presented a case of cerebral tumor cured by operation. The patient was a sailor by occupation and three years previously had fallen on shipboard. The fall rendered him unconscious and he remained so for 36 hours. So pronounced was this state that his companions considered him dead and were about to throw him overboard. He gradually regained consciousness and no motor disturbances followed. Some time after this he began to have headaches which persisted off and on. In addition, in the past three or four months he had had a sticking or pricking sensation in the left face. His eyes were examined and it was said that the discs were a little swollen. About a week before entering hospital his headaches became very severe. There was no other complaint. Eyes at this time were reported normal. Headache persisted, and 48 hours before entrance he began to get confused and walking became slightly difficult. These two symptoms persisted and within twenty-four hours he was semi-conscious and walked with much difficulty. He was admitted to the Institute the evening of December 10, 1912. He was in a state of semi-consciousness, very restless, tossing himself about the bed. Physical examination under difficulties revealed a beginning left hemiplegia. His gait suggested a beginning paraplegia. Spinal puncture revealed pressure, 5 cells, excess of globulin, and Fehling reduced, Wassermann negative. Eyes showed R 5 D., L 4 D. The following morning craniotomy was done by Dr. A. S. Taylor.

Dr. Taylor said that since the tumor was thought to be in the right frontal lobe, but might be situated posteriorly, a large osteoplastic flap was turned down by means of the Hartley-Kenyon motor saw, which would permit a thorough exploration, and could readily be removed in part or in whole, if necessary for decompressive purposes. This flap extended from just in front of the ear upward vertically to within 3 c.m. of the sagittal line, then forward well on to the frontal bone, and then downward and backward to just above the anterior end of the zygoma, thus bringing the hinge of the flap in the thin squamous bone. On turning down the bone flap the dura was very tense and showed no pulsation. Stellate incisions were made in the dura for decompressive purposes. The frontal lobe was explored and no tumor found. On examining the upper posterior corner of exposed brain, just the anterior edge of a solid tumor was made out. Further examination disclosed a large solid tumor occupying most of the right parieto-occipital lobe. This lay beneath the bone behind the osteoplastic flap which had been turned down. The removal of the tumor was left for a second stage. The segments of dura were placed smoothly over the brain surface, the lower third of the bone flap was removed for decompressive effect, and the remainder was returned to its proper position. The muscles and scalp were sutured. No drainage was used. This procedure left a considerable area for decompression beneath the thick belly of the temporal muscle and also left the upper part of the bone flap floating so that ample decompression was provided. The following day the patient was perfectly conscious, sat up in bed and demanded a smoke. His eye grounds rapidly improved, the signs of left hemiplegia disappeared, and his mind became clear. On Dec. 21 (ten days after the first operation), a second flap was turned down just posterior to the first one. The inner table of this flap showed several rough projections of bone which had caused an ulceration of the dura, and this ulcerated area was apparently the center and original starting point of the tumor. The tumor, about the size of an ordinary fist, was easily shelled out of the parieto-occipital lobe. Its anterior edge pressed far enough forward to compress the motor cortex. The bone which was evidently diseased was stripped from the soft part of the flap, which was then sutured in place by layer sutures. The dura overlying the tumor was removed with it. A small wick of gauze was inserted into one corner of the wound. Healing was by primary union; the eyes had made a perfect recovery and the only evidence left of his trouble, besides the scars, consisting of some astereognosis in the fingers of the left hand.

Dr. Connor asked Dr. Taylor if the growth extended so far posteriorly as to involve the visual center in the occipital lobe, as would be indicated by a hemianopsia.

Dr. Bryant asked whether one might expect to find blood pressure high in such a case, and whether the tumor had been long in existence.

Dr. Brannan asked whether the removal of the tumor restored function, and if this were a spindle-celled sarcoma.

Dr. Ewing asked if a positive diagnosis had been made in this case between a sarcoma and an endothelioma.

Dr. Wood said that this was an encapsulated tumor, and that in the brain the endotheliomata and sarcomata resembled each other greatly in morphology.

Dr. Taylor said in reply to Dr. Conner that the patient was unconscious when brought to the Neurological Institute. He thought that for a short time there was a little hemianopsia. In reply to Dr. Bryant he said that slow growing tumors that occurred outside the brain and grew inward developed symptoms very slowly. They might be there for years before causing any symptoms. The blood pressure would be high in such a case. Such motor disturbances as the patient had were the result of the anterior end of the tumor pressing against the motor cortex; as soon as that was released the recovery of function was immediate. The sister of the patient stated that the patient had been bothered with his eyes for ten years. Whether that had anything to do with the brain tumor or not could not be definitely stated, but it was not probable. The fall on the head had probably injured the inner table of the skull. The bone itself was diseased and was removed. There was a distinct place one-half inch in diameter where two or three rough places could be seen. His fall may have cracked the inner table of the skull and constant irritation of the dura may have started this growth which pushed down into the brain substance.

**Fatal Case of Bichloride of Mercury Poisoning.**—Dr. Kinnicutt gave the clinical history of a fatal case of bichloride of mercury poisoning, with specimens. The patient, a woman 32 years of age, was admitted to his wards in the Presbyterian Hospital an hour after the swallowing of the poison. The history given by the patient was that almost immediately after taking two glasses of beer, she was seized with a violent pain in the epigastrium, followed in a few minutes by the vomiting of bright fluid blood. She was brought to the hospital in an ambulance, and during the succeeding 24 hours had several small hematameses and passed several ounces of fluid blood by the rectum. Examination revealed no lesions of the mucous membrane of the mouth or pharynx, no physical signs other than sensitiveness in the epigastrium at about the site of the pylorus. It was believed that she was suffering from a gastric or duodenal ulcer. On the third day after admission slight superficial sloughs developed on the hard palate and inner surface of cheek on one side. Gradually marked sensitiveness developed along the whole course of the colon, there were frequent vomiting (the

vomited matter being free of blood), and profuse diarrhœa, the stools containing blood in small amounts and finally shreds of necrotic tissue. A diagnosis of poisoning by some metallic poison was then believed to be the correct one, although the patient positively adhered to the history first given. There was complete anuria for seven days without the development of uremic symptoms of any kind. The blood, however, showed the presence of urea 0.245 per cent. (normal 0.02 to 0.04 per cent.), and NaCl 1.984 per cent (normal 0.6 per cent); it failed to reveal the presence of mercury, which was the poison suspected of being the cause of the symptoms. Also, no mercury was recovered either from stools or urine. On the eighth day a small amount of urine was passed, and gradually the renal function was restored so far as the excretion of urine was concerned. The symptoms referred to practically continued to be present up to the time of death, without the development of new ones. Death occurred on the thirteenth day from the beginning of the illness. Shortly before death the patient confessed to having taken three bichloride of mercury tablets, probably containing about 25 gr. of the bichloride of mercury altogether with the beer. An autopsy was made by Dr. Albert Lamb. The specimens exhibited—esophagus, stomach, small and large intestine, and kidneys—showed interesting lesions. *Esophagus:* In general the mucous membrane was pale and intact; there were, however, scattered diffuse areas of rather intense congestion. *Stomach:* The mucous membrane was intensely congested; the contrast between the lower end of the esophagus and the beginning of the stomach was striking, the esophagus being pale, and the stomach intensely red; on the greater curvature there was an ulcerated area about 7 c.m. by 6 c.m. covered with greenish black necrotic tissue. The duodenum showed only a moderate amount of congestion, and the same was true of the remainder of the small intestine. The transition at the junction of the ileum and cecum presented a striking picture. In the terminal portion of the ileum the mucous membrane appeared fairly normal. From this point, which was sharply defined, an intense diphtheritic inflammation extended continuously as far as, and even into, the rectum. Microscopic examination revealed a complete necrosis of the coats of the large intestine, down to the muscularis, which in places also was involved in the process. *Kidneys:* An acute parenchymatous nephritis was present. Microscopically the lime deposits were very striking. In places these existed as small granules within the epithelial cells of the tubules, at other points they almost completely replaced the cells, and again the lumina of the tubules were choked with masses of them. Dr. Kinnicutt said that the specimens strikingly demonstrated the interesting election of the large intestine in the elimination of the poison.

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, Held December 16, 1912.*

The President, Dr. Reynold Webb Wilcox, in the Chair.

**Nominations for Officers.**—The following nominations for officers were made: *Recording Secretary,* Dr. P. Brynberg Porter, Manhattan; *Chairman for the Borough of Brooklyn,* Dr. Robert E. Coughlin, Brooklyn; *Chairman for the Borough of Richmond,* Dr. William Bryan, West New Brighton, S. I.; *Member of Council,* Dr. Louis Faugères Bishop, Manhattan.

**Experience with Neosalvarsan.**—Dr. Howard Fox, who read this paper, stated that he wished his remarks on neosalvarsan to be considered as a preliminary report and to serve as a means of introducing the subject to the attention of the Society. He did not wish to quote from the work of others, but to give his own experience with the samples of neosalvarsan given him for experimental purposes by Professor Ehrlich. The remedy had been used entirely for charity patients at the Harlem Hospital, all of them having been treated in an ambulatory manner. Thus far fifty patients had received the neosalvarsan, in the majority of the cases by the intravenous method. Most of the injections had been given on three or four successive occasions, at intervals of forty-eight hours. The cases included various early and later syphilides, lesions of the mucous membranes of the eye and of the bones. The writer's impression was that the effect of neosalvarsan was slightly less rapid than that of the old salvarsan. There was no question but that the administration of the new preparation was easier than that of salvarsan. There also seemed to be less disturbance in the veins following the injection, as it was often possible to give four injections in the same vein without causing its obliteration. The effect upon the Wassermann reaction had not been particularly favorable. The reading of the paper was followed by a demonstration of patients illustrating some of the results that had been obtained. These included a case of iridocyclitis which occurred during the course of treatment of an early syphilide.

Dr. John A. Fordyce said that he began the experimental use of neosalvarsan at the City Hospital in the spring of 1912, and at that time gave about 400 doses of it. It was then advised by Schreiber to administer the drug in doses of from one gram to one gram and a half every alternate day until four doses had been given. He had given the amount of the drug advised by Schreiber to a number of patients, to others the drug was given in smaller amounts. About one-half of the patients to whom the larger doses were given developed febrile reactions, sometimes after the first dose, though generally after the third dose. The distilled water then employed was not always freshly prepared on the day it was used. This might have accounted in part for the reactions. In his private work the water was distilled on the day of its use and he now had fewer and fewer reactions. He believed that the clinical results following the administration of neosalvarsan were almost, if not quite as rapid, as those following the administration of salvarsan if given in somewhat larger proportional doses, and showed photographs of several cases illustrating the rapid effects of the drug on the early and late syphilitic manifestations. Since the earlier experimental use of neosalvarsan it had been found advisable to lengthen the intervals between the doses and to diminish somewhat the quantity of the drug employed. He was now giving it in doses of 0.45 to 0.8 gm. and repeating it at weekly intervals. Up to the present time he had given more than 1,000 doses of neosalvarsan. With the improvement in the technique, he scarcely noted any reaction except in the florid stage of the disease. In two patients to whom 6 and 7 grams of neosalvarsan had been given in a period of two weeks he had observed symptoms of irritation of the peripheral nerves, which was manifested by quite marked paresthesias of the extremities, persisting for several weeks and then gradually disappearing. The neosalvarsan, according to his experience and that of other observers, seemed to have more of a neurotropic action than salvarsan. Dr. Fordyce went on to say that the treatment of syphilis was now more severely criticised than under the older methods of treatment. We not only combatted the clinical manifestations, but endeavored to obtain a persistent negative serum reaction, and as our knowledge of syphilis of the nervous system increased, a negative blood Wassermann was not sufficient. We should endeavor in syphilis of the nervous system to secure the same in the fluid obtained by spinal puncture, as it was not infrequently noted that the Wassermann reaction was negative in the blood and positive in the spinal fluid, and *vice versa.* He did not doubt for an instant that under the newer methods of treatment far better results were obtained than under the older ones. This was evidenced not only by the quick response of the lesions to the treatment, but also by a smaller number of relapses sand the growing infrequency of reinfections. Since the introduction of salvarsan two cases of reinfection had come under his observation. In one of them, a young man who presented typical multiple initial lesions of the lips and a secondary rash, a single injection of salvarsan was given in June, 1910; after which the Wassermann reaction became negative and remained so for nearly two years. During the present summer the patient presented himself with an initial lesion on the penis from which spirochetes could be demonstrated. He later developed a secondary rash on the skin and mucous patches in the throat. In the second case, after apparent cure of his first infection and with a negative Wassermann reaction, the patient developed a second chancre, from the secretion of which spirochetes could be demonstrated. Dr. Fordyce was not informed of the subsequent developments in the second case. The treatment of syphilis was now to some extent standardized, and we could assure a patient, if seen in the early period of the infection, that the course of treatment could be materially abbreviated. The method which he employed was briefly as follows: In the early period of the disease, from four to six injections of salvarsan at weekly intervals, followed by two to three months of mercurial injections or rubbings. A period of rest of six weeks or two months; then a Wassermann reaction. If the latter were positive, a repetition of two or three intravenous injections of neosalvarsan, followed by mercury. He had an increasing number of cases in which this treatment had apparently aborted the infection within

the first six months. In the later periods of the disease the methods of treatment were much the same, but there was less certainty of permanently altering the serum reaction except by several courses of the treatment which had been outlined. In latent syphilis with a positive Wassermann reaction it was sometimes exceedingly difficult or quite impossible to change the reaction except by an amount of arsenic or mercury which would be considered dangerous to the patient. It was possible that in such cases the virus was so permanently fixed to the cells of the body that no method of treatment could change it. To illustrate this latter statement he referred to a patient with severe syphilis of the nervous system to whom 18 injections of salvarsan and neosalvarsan had been given, together with more than 100 injections of bichloride and salicylate of mercury and several courses of iodide of potassium in large doses. The reaction in this case remained persistently positive, although the clinical symptoms showed marked improvement. In regard to the so-called nerve recurrence he was more firmly convinced than ever that they were due to insufficient treatment, and not to the effect of the drug on the cranial nerves. Since salvarsan had been used in the intensive manner outlined nerve recurrences were less frequently reported. Lumbar puncture, too, in such cases, had proved that a meningitis existed which was doubtless responsible for the involvement of the special nerves. It was important to recognize the fact that the nervous system is infected at a very early period of the disease, as spinal punctures made at this time showed that the fluid contains an increase of lymphocytes and globulin, and gives a positive Wassermann reaction. This serological condition might exist without symptoms. It was very easy to see, however, that such patients were potentially in a position to develop meningitis with involvement of the cranial nerves, and later the inflammatory and degenerative processes met with in tabes or paresis. Unless all the spirochætæ were destroyed, as evidenced by the return of the spinal fluid to a normal condition, permanent damage which could not be repaired might easily result. The observations of the best neorologists who were familiar with the proper treatment of syphilis of the nervous system, and who had opportunities of treating large numbers of patients, showed that insufficient treatment with salvarsan was worse than insufficient treatment with mercury. The best results in such cases were obtained by frequent repetition of salvarsan combined with injections of mercury. An increase in tabetic symptoms following one or two doses of the drug was not an indication that it is harmful but was an indication for pushing the treatment to greater length, as such cases would show improvement after a sufficient amount of the drug had been given. He had been unable to convince himself that either salvarsan or neo salvarsan had any special effect on the optic or auditory nerve; or that they hastened the degenerative processes which previously had existed in these nerves.

Dr. Faxton E. Gardner said he had employed neosalvarsan exclusively since the first of May last, since which time he had given about 200 injections. All of these were intravenous, and he had never used the intramuscular method for either the old or the new salvarsan, holding that, up to date, no advantage of intramuscular injections over intravenous had been demonstrated, while the disadvantages were obvious. Moreover, in all his cases he had jabbed the vein directly under the skin; and he had never been obliged to expose the vein. In one, instance, however, he had found it impossible to get into the vein, because of infiltration of the arm in consequence of two previous injections by others. He therefore gave up the attempt. In order to be sure of fresh distilled water for the injections, he always distilled his own water. He was not prepared to say that all the reactions which had been noted after the use of neosalvarsan were due to the character of the distilled water employed, but he was convinced that this was responsible for a good share of them. When it came to injecting a fluid into the human body, certainly only the purest that could be obtained should be used. In five of his cases vomiting was noted, and in three of these that occurred consecutively he found that the distilled water of the injections, which at the time he thought was fresh, was in reality two weeks old. He had never had a case of infiltration. When leakage occurred during the injection there always was great pain, and we could therefore judge from the pain when there was leakage that would later lead to infiltration. In that case it was advisable to withdraw the needle at once and to make a new puncture elsewhere, either in the same arm or in the other. It was an important point to dry up thoroughly the inside of the needle, as well as cleaning the outside after the injection, and for this purpose he was in the habit of employing the blowing bulb of the thermocautery. Neosalvarsan, he believed, was certainly less *toxic* than salvarsan, but also less *active*. While the results with it were sometimes brilliant, in other instances its action seemed slow, and in still others little, if any, benefit was noted. Personally, he would not employ the massive doses commonly given in Germany, and thought that better results would be obtained by lengthening the period of treatment, instead of simply increasing the doses.

Dr. Abraham L. Wolbarst said that he had treated 120 cases with neosalvarsan. To these 120 patients he had given 51 intramuscular injections and 90 intravenous injections. Intravenous injections were easy to give and easy to take, but he had found them decidedly less efficient than the intramuscular. With the latter the arsenic had a long-continued action, so that the drug could be found in the tissues even for three months after its administration. With intravenous injections, however, the effects were far less lasting. Their duration was a matter only of days—four, five or six days, and eight days as the maximum. Another decided disadvantage of them was the scar sometimes left after cutting down on a vein in order to get the injection into it. Thus, he had seen one young girl who had such a scar on her arm that she was mutilated for life, and he could not but feel that if the operator was unable to puncture the vein without cutting, he should have given up the attempt to use salvarsan and treated the patient with mercury. Such scarring was unpardonable and should, he thought, be considered as malpractice. He understood that examiners for life insurance companies were now in the habit of looking for scars on the arms of applicants for insurance as one means of determining whether they had had syphilis or not. If the surgeon could not get into the vein without first cutting down upon it, he had better either employ intramuscular injections or else give mercury. In a conversation which he had had some eight months ago with Ehrlich, the latter had expressed the opinion that the intramuscular injection would eventually be the only method used for the administration of salvarsan and neosalvarsan if a painless method could be devised. Personally, he had found the simple distilled water, which he employed for the intramuscular injections at first, extremely painful. He therefore modified the method by suspending the product in 3 c. c. of pure glycerin, to which was added 1 c. c. of a watery solution of some anesthetic, such as alypin and novocaine. There was thus produced about 4 c. c. of fluid which would go through a moderate-sized needle, and he found that with this there was usually comparatively little pain from the injection. It was his practice to make four punctures in the buttocks, two on each side, so that there was thus one puncture for each quadrant of the part. From 70 to 90 per cent. of the injections were comparatively painless. In making them it was important to avoid the ramifications of the sciatic nerve. Sometimes it would be found that while three injections were painless, the fourth would cause a very considerable amount of pain. In one instance an abscess had formed, in consequence of infection of the puncture. The great advantage of the intramuscular method was, as he had said, that its effects were much more permanent than those of the intravenous. In cases in which he had employed intramuscular injections of salvarsan more than two years ago, he had found that there had been no return of the disease. But in a disease like syphilis this was far too short a period on which to base any conclusions as to the completeness of the cure. It was only after long years of waiting that the question could be definitely settled, and it was entirely unfair to both Ehrlich and Wassermann to speak of a "cure" after one or two months of treatment, even though the Wassermann reaction be negative.

Dr. Fox, in closing, said he had been pleased to hear of Dr. Fordyce's experience with the intensive treatment, and to learn that in one of his cases he had given as many as eighteen doses of salvarsan, old and new. It seemed to him probable that by the use of massive doses the best results were to be obtained. Dr. Gardner was right, he thought, in regard to ambulatory patients. It was entirely safe to treat a patient at one's office or in the dispensary, and then let him go home. Dr. Wolbarst was quite justified in considering it culpable to cut down upon the vein. The needle should be inserted directly through the skin, when possible, as the scars resulting from cutting down upon the veins were often unsightly, as well as compromising.

**The Massive-Dose X-Ray Method of Treating Skin Diseases.**—Dr. George M. MacKee made an address on this subject. He prefaced his remarks by stating that the former term, "single-dose method," was too misleading

and spectacular. The question of a suitable name for the method had been discussed at a recent meeting of the New York Roentgen Society. Three terms had been considered, namely, single-dose, massive-dose and measured-dose *x*-ray method. The preference had been given to the second title. The remarks would be limited to a description of the method as employed in the treatment of dermatological disorders. Holzknecht, Kienböck, Benoist, Sabouraud and Niré and others deserve the credit of making it possible to measure the dose of the *x*-ray administered. The speaker disclaimed any originality in the work, with the exception of a few pertinent suggestions and a few modifications in technique. The method consisted of judging the dose of *x*-ray required to cure a given lesion of the skin and to administer this dose at one sitting. Occasionally, as in hyperidrosis and keloid, the curative dose was so large as to preclude its administration in one treatment, on account of the severe reaction that would follow. In such instances the dose could be divided into two or three treatments. As a matter of fact, however, there were comparatively few cutaneous disorders, if amenable to radiotherapy at all, that could not be controlled by one application of the ray. The technique consisted of measuring the quality of the ray by the use of the Benoist penetrometer, the parallel spark-gap, and the milliamperometer. The quantity of the ray was estimated by the Holzknecht radiometer. The various instruments employed in the technique were demonstrated by lantern slides. The speaker then considered the dermatological diseases that were amenable to treatment by this method. Lantern slides were shown of epitheliomata, lupus vulgaris, tinea tonsurans, tinea barbæ, inveterate localized eczema and psoriasis, verruca, cornu, corns, etc., that had been cured by one treatment. Examples of keloid and hyperidrosis that had been cured by from two to four treatments were also demonstrated. He was of the opinion that if every dermatoloical clinic of the Department of Health would institute a modern radiotherapeutic department and would epilate the entire scalp in every case of ringworm that the disease would soon be very uncommon, as was the case in France and England. The following hypothesis was offered in explanation of the good results obtained in epithelioma: The former fractional-dose method caused the application of a much greater quantity of ray than was necessary to effect a cure. This produced a localized immunity to the ray; in other words, by the oft-repeated, small doses the malignant cells were taught to resist the beneficial influence of the ray. With the new method, on the other hand, only the exact quantity of ray necessary to produce a cure was administered. In conclusion, Dr. MacKee said he desired to thank Dr. Fordyce, to whom he had the honor to be a clinical subordinate at the New York University and Bellevue Medical College, for his kindness in allowing unlimited opportunities for research work.

Dr. James McFarlane Winfield said that he had not had any personal experience with the single-dose administration of the *x*-ray, although he had used radiotherapy in his dermatological practice for many years, and that latterly he, with many other cutaneous specialists, had not used it as much as formerly, because of the uncertainty of its action, unless all of the scientific improvements were understood and employed. He felt that Dr. MacKee deserved a great deal of credit for bringing this method of administration of the ray to the notice of the profession, for while this method was used in Europe, Dr. MacKee was the pioneer in this country. The demonstration of the evening had made the matter so clear that it would seem as though any one who was inclined to treat disease by the ray could have derived a great deal of information. There were a few points he wanted to emphasize. Radiotherapy should only be practised by those expert in radiotherapy. This was a distinct branch of *x*-ray technic and it had been demonstrated many times that an expert radiographer was not necessarily a good radiotherapist. It was also essential that one practicing radiotherapy should be a thoroughly trained physician. It was not safe to entrust our patients to one who simply knew how to run the *x*-ray and since nearly all of the diseases that were treated by the ray were dermatological, either the operator should be one trained in dermatology or the cases should be under the direct supervision of one so trained.

Dr. Fred Wise said that his experience with the method had been limited. He had, however, used to some extent the Sabouraud pastiles and, like others in the United States, followed the rules laid down by the European authorities. He thought Dr. MacKee was altogether too modest in his statements. He had certainly worked very hard in this matter, and deserved great credit for the results which had been accomplished.

Dr. John Remer, having referred to the technical management of the tubes employed, said that among the advantages of the massive-dose method were its painlessness and the slight amount of scarring. As a result of the ordinary use of *x*-ray treatment, a very disfiguring scar often remained, but with this method there was scarcely no scarring at all.

Dr. Joseph Friedmann said that the greatest difficulty was the matter of dosage. However, the methods described by Dr. MacKee, though not accurate, served our purpose at present. As a rule, he personally did not use single-dose treatment in cases of epithelioma, but small and repeated doses. In some instances single-dose treatment caused severe burns, which were very painful and healed with difficulty. In May, 1910, he had presented at the New York Post-Graduate Medical School sixteen cases of cured epithelioma, in patients ranging from 45 to 80 years of age; and in from six months to a year he had had five recurrences. At the Post-Graduate they had had good results in treating epithelioma, as about 90 per cent. of cases were cured. For the past two years he had found that under the employment of thorough fulguration, followed by *x*-ray treatment, the cure of this condition was more rapid. In epithelioma with glandular involvement of an inflammatory nature the *x*-ray was best, but if the glands showed malignant degeneration it was preferable to use the knife first, and then the *x*-ray. At the Mount Sinai Hospital Dispensary excellent results had been obtained in trichophytosis capitis. One single *x*-ray dose was given, a Sabouraud pastile being employed until complete color change was present, namely, from greenish-yellow to dark brown, which usually occurred in from twelve to eighteen minutes. Sometimes, however, he discontinued the application before the color change was entirely completed. During this procedure the head was covered with a rubber shield having an opening a little larger than the diseased area, which shield also covered the shoulders of the patient. If the disease were very extensive, different areas were treated separately, and after the epilation was complete he was accustomed to order the use of oleum rusci and oleum olivae, 1 to 3, to be applied with the skin brush every night, to stimulate the circulation. For warts he employed fulguration, without any *x*-ray treatment, and with excellent results. If they were large, and with a broad, flat base, he applied, before the fulguration, a 20 per cent. solution of potassium hydroxide. This procedure was less painful and easily destroyed the growth.

Dr. MacKee, in closing, said that Dr. Winfield had brought up a very important point. The speaker had made the remark that the radiotherapeutist, to obtain and maintain the confidence of the medical profession, and especially that of the dermatologist, in the *x*-ray treatment of the cutaneous affections, must be well versed in dermatology. Cases were frequently referred to the radiotherapeutist with a diagnosis of cutaneous tuberculosis, epithelioma, etc., and which turned out to be syphilis, blastomycosis or some other affection. For the purpose of statistics, scientific observation, and treatment, it was necessary, the speaker said, to establish the diagnosis before treatment was instituted. Dr. Winfield's suggestion that the dermatological cases be submitted to a dermatologist for diagnosis before going to the radiotherapeutist was a very good one, and opened the field to all who made a specialty of radiotherapy. In the time at his disposal it had been impossible to more than outline the massive-dose *x*-ray method. For those who were interested enough to attempt its use he would advise experiments in radiography in order to become thoroughly familiar with the various types of exciting apparatus used and with the physical properties of the *x*-ray. The next step would be to carry out *x*-ray biological experiments on animals, and finally to become thoroughly familiar with the special measuring apparatuses before attempting to treat the human being. The massive-dose method required a great deal of attention to detail of technique, as well as watchfulness, judgment, and common sense; it required years, the speaker said, to develop a radiologist. If the technique were correct the method was sufficiently exact for all practical purposes, but it was far from being foolproof. The speaker had had seven years of experience with the method. At first only a few cases were treated each year because of inferior apparatus, but in the last three years all his dermatological cases which had received *x*-ray treatment had been given the benefit of the massive-dose method. Not only was this method of administering the ray more scientific, but the results were superior to the former fractional-dose method. In regard to the treatment of ringworm of the scalp, he was convinced that it was necessary to epilate

the entire scalp in nearly every instance. This could be accomplished in four exposures at a single sitting. It was not possible to epilate the entire scalp with one exposure, on account of the convexity of the skull. By dividing the scalp into four parts the slight convexity in any one field would not be enough to seriously interfere with the equality of the dose. In private practice a patient having a small and localized ringworm of the scalp need not necessarily be completely epilated. In such a case the mother would have intelligence enough to prevent the diseased hairs from mingling with and infecting the hair of other portions of the scalp, but in dispensary work the speaker had found it absolutely essential to epilate the entire scalp at the first treatment. In cases where there was only a single lesion and this was the only area epilated, and the disease later became disseminated, as it usually did, and where the new hairs in the cured area had become reinfected, it was necessary to wait several weeks before it would be safe to epilate the entire scalp, for fear of obtaining a permanent alopecia. In the meantime the little patient would be a constant menace to others. Unquestionably the proper thing to do was to epilate the entire scalp of every charity patient afflicted with tinea tonsurans unless the disease showed an unmistakable tendency to remain localized, as was sometimes the case, particularly in children near the age of puberty. The speaker said that he would like to have gone into the massive-dose method of treating internal disorders, and to have discussed the filtered ray and the dehematization of the skin, but time had not permitted the introduction of these subjects.

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DAS ZWEIKINDERSYSTEM. By Dr. Julius Wolf. 36 pages; paper; price, 1 Mk. August Hirschwald, Publisher, Berlin.

SKIN GRAFTING. By Leonard Freeman, B.S., M.A., M.D. 139 pages; illustrated; cloth; price, $1.50. C. V. Mosby Company, Publishers, St. Louis.

SEMI-ANNUAL REPORT OF SCHIMMEL & CO.

DISEASES OF THE THROAT, NOSE, AND EAR. By W. G. Porter, M.B., N.Sc., F.R.C.S. 275 pages; illustrated; price, $2.50 net. William Wood & Company, Publishers, New York.

PATHFINDERS IN MEDICINE. By Victor Robinson. 317 pages; illustrated; cloth; price, $2.50. Medical Review of Reviews, Publishers, New York.

A SYSTEM OF CLINICAL MEDICINE. By Thomas Dixon Savill, M.D., 942 pages; (third edition); illustrated; cloth; price, $4.00 net. William Wood & Company, Publishers, New York.

DIE EXSUDATIV-LYMPHATISCHE DIATHESE. By Dr. Paul Sittler. 111 pages; paper; price 3.50 M. Curt Kabitzsch, Publisher, Wurzburg.

UBER LAPARO- UND THORAKOSKOPIE. By Dr. H. C. Jacobaeus. 170 pages; illustrated; paper; price 6 M. Curt Kabitzsch, Publisher, Wurzburg.

BREWING. By A. Chaston Chapman. 128 pages; illustrated; cloth; price, 40c. net. G. P. Putnam's Sons, Publishers, New York.

THE PSYCHOLOGY OF INSANITY. By Bernard Hart, M.D. 176 pages; cloth; price 40c. net. G. P. Putnam's Sons, Publishers, New York.

THE INDIVIDUAL IN THE ANIMAL KINGDOM. By Julian S. Huxley. B.A., 167 pages; illustrated; cloth; price, 40c. net. G. P. Putnam's Sons, Publishers, New York.

UBER EINE UNRUHEERSCHEINUNG: DIE HALLUZINATION DES ANRUFES MIT DEM EIGENEN NAMEN. By Dr. Max Lowy. 131 pages; paper. Franz Dauticke, Publisher, Leipzig.

DIE BEHANDLUNG DER KNOCHEN UND GELENKTUBERKULOSE MIT ORTHOPÄDISCHEN MASSNAHMEN. By Dr. F. Oehlecker. 90 pages; illustrated; paper; price, 3 M. Curt Kahitzsch, Publisher, Wurzburg.

TUBERCULIN IN DIAGNOSIS AND TREATMENT. By Louis Hamman and Samuel Wolman. 381 pages; illustrated. D. Appleton & Company, Publishers, New York.

ESSAI SUR LE TRAITEMENT DES CYSTITES PAR L'ENFUMAGE IODE. By Dr. Gaston Farnarier. 45 pages; paper. Printed from *La Semoine Medicale.*

THE SURGICAL DISEASES OF CHILDREN. By William Francis Campbell, A.B., M.D. and LeGrand Kerr, M.D. 693 pages; illustrated; cloth; D. Appleton & Company, Publishers, New York.

VIAGGIO DA TRIPOLI DI BARBERIA. By Dott. Paolo Della Cella. 147 pages; paper. Citta Di Castello, Publisher.

PROGRESSIVE MEDICINE. Vol. XIV, No. 4. Edited by Hobart Amory Hare, M.D. and Leighton F. Appleman, M.D., 381 pages; illustrated; paper; price, $6.00 per annum. Lea & Febiger, Publishers, New York.

BUILDING A PROFITABLE PRACTICE. By Thomas F. Reilly, M.S., M.D., 290 pages; illustrated; cloth; J. B. Lippincott Company, Publishers, Philadelphia.

HEREDITY, EVOLUTION, AND VITALISM. By RONALD CAMPBELL MACFIE, M.A., M.B., C.M.; price $2.50 net; cloth; 302 pages. William Wood & Company, Publishers, New York.

THE INTERNAL SECRETORY ORGANS: THEIR PHYSIOLOGY AND PATHOLOGY. By Prof. Dr. ARTUR BIEDL. Introductory Preface by LEONARD WILLIAMS, M.D., M.R.C.P. Translated by LINDA FORSTER. Price $6.00 net; cloth; 586 pages. William Wood & Company, Publishers, New York.

A COMPEND OF HISTOLOGY. By HENRY ERDMANN RADASCH, M.Sc., M.D. Third edition; illustrated; cloth; 363 pages; price $1.25 net. P. Blakiston's Son & Co., Publishers, Philadelphia, Pa.

FORTY-THIRD ANNUAL REPORT OF THE STATE BOARD OF HEALTH, MASSACHUSETTS. Illustrated; cloth; 680 pages. Wright & Potter Co., State Printers, Boston, Mass.

A MANUAL OF IMMUNITY. By ELIZABETH T. FRASER, M.D. 199 pages; cloth; price $1.60 net. James MacLehose & Sons, Publishers, Glasgow.

LECTURES ON CLINICAL PSYCHIATRY. By Dr. EMIL KRAEPELIN. Revised and Edited by THOMAS JOHNSTONE, M.D., Edinburgh, M.R.C.P., London. Third edition; price $3.50 net; cloth; 368 pages. William Wood & Company, Publishers, New York.

TRANSACTIONS OF THE THIRTY-FOURTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION. Illustrated; cloth; 358 pages. Published by the Association, New York.

DIE KRANKHEITEN DER MUNDHÖHLE: DES RACHENS UND DER NASE. By Dr. L. GRÜNWALD. Price 12 Mk.; illustrated; cloth; 801 pages; third volume. J. F. Lehmann's Verlag, Munchen.

EXPERIMENTAL PHYSIOLOGY. By E. A. SCHAFER, F.R.S. Illustrated; cloth; 111 pages; price $1.35 net. Longmans, Green & Co., Publishers, London.

THE STORY OF A DOCTOR'S TELEPHONE. By ELLEN M. FIREBAUGH. Price $1.25 net; cloth; 239 pages. The Roxburgh Publishing Co., Boston, Mass.

SAFEGUARDING THE SPECIAL SENSES. By HENRY O. REIK, M.D. Illustrated; cloth; 123 pages; price 25c net. F. A. Davis Company, Publishers, Philadelphia.

HEALTH AND LONGEVITY THROUGH RATIONAL DIET. By Dr. ARNOLD LORAND. 416 pages; cloth; price $2.50 net. F. A. Davis Company, Publishers, Philadelphia.

SURGICAL OPERATIONS WITH LOCAL ANESTHESIA. By ARTHUR E. HERTZLER, M.D. Price $2.00 net; 205 pages; cloth; illustrated. Surgery Publishing Company, New York.

THE SOLDIER'S FOOT AND THE MILITARY SHOE. By EDWARD LYMAN MUNSON, A.M., M.D. 147 pages; illustrated. The U. S. Cavalry Association, Kansas.

A GUIDE TO THE DESCRIPTION OF MICROSCOPIC SECTIONS OF PATHOLOGICAL TISSUES. By O. C. GRUNER, M.D. Paper; price 35c; 20 pages. Published at Miss Poole's Bookroom, Montreal, Canada.

AN ATLAS OF THE DIFFERENTIAL DIAGNOSIS OF THE DISEASES OF THE NERVOUS SYSTEM. By HENRY HUN, M.D. 290 pages; cloth; price $4.00. The Southworth Company, Publishers, New York.

TRAITE DE L'EXAMEN DES CRACHATS. By FERNAND BEZANCON and S. I. DE JONG. 411 pages; paper; illustrated. Masson et Cie., Editeurs, Paris.

LA GROSSESSE EXTRA-UTERINE PRECOCE. Par le Dr. LUCIEN HENAULT. 134 pages; paper. Hayez, Imprimeur des Academies Royales de Belgique. Bruxelles.

SURGERY FOR DENTAL STUDENTS. By ARTHUR S. UNDERWOOD, M.R.C.S., Eng., L.D.S., Eng., and BAYFORD UNDERWOOD, M.B., B.S., London, L.R.C.P., M.R.C.S., Eng. 244 pages; cloth; price $1.50 net. William Wood & Company, New York.

THE CARE AND TREATMENT OF EUROPEAN CHILDREN IN THE TROPICS. By G. MONTAGU HARSTON, M.D., London, M.R.C.S., Eng., L.R.C.P., London, with introduction by Sir PATRICK MANSON, G.C.M.G., M.D., LL.D. 232 pages; illustrated; cloth; price $3.00. William Wood & Company, New York.

## Therapeutic Hints.

**Treatment of Enuresis.**—M. T. Schnirer in presenting a summary of the modern treatment of this condition states that all possible reflex exciting causes should be investigated and those present should be removed. No fluids should be allowed in the child's evening meal. The foot of the bed should be elevated so as to raise the pelvis of the patient. The latter should be made to urinate before retiring and should sleep in the side position. Faradization of the bladder may be resorted to: one electrode may be placed over the hypogastrium and the other on the perineum or high in the rectum; or the latter electrode may be in the form of a metallic sound, covered up to the tip with caoutchouc, and introduced into the bladder. Massage of the neck of the bladder may be employed, the patient being in the knee-chest position, and the physician's finger in the rectum pressing at first lightly and later firmly toward the neck of the bladder. In certain intractable cases success has followed the use of epidural injections in the sacral region of 10 centimeters of a 0.6 per cent. solution of sodium chloride. The following represent some of the forms of medication that have been employed:

℞ Extr. belladonn., 0.10 gram.
Sacch. alb., 2 grams.
M. f. pulv. div. in dos. X. S. One powder t. i. d.

℞ Extr. belladonn.,
Nucis vomicæ, āā 0.08 gram.
Ferri hydroxidi, 0.4 gram.
Sacch. alb., 3 grams.
M. f. pulv. div. in dos. VIII. S. One powder daily. (Faure.)

℞ Fl. extr. rhoid. arom., 20 c.c.
S. 15 drops t. i. d.

℞ Ergotin., 1 gram.
Aq. destill., 70 c.c.
Syr. rub. id., 20 c.c.
S. One teaspoonful every 2 hours.

℞ Natr. brom.,
Ammon. brom., āā 2.50 grams.
Aq. destill., 100 c.c.
S. One tablespoonful to be taken in milk at night. (Heubner.)

℞ Extr. ergotæ, 0.2 gram.
Extr. nucis vomicæ, 0.1 gram.
Aq. destill., 5 c.c.
S. 10 drops two or three times a day. (Biedert.)

℞ Lupulin,
Ferri carbonat. saccharat.,
Sacchar. alb., āā 6 grams.
S. A tip of a knife blade t. i. d. (Gerhardt.)

℞ Strychnin. nitrat., 0.02 gram.
Aq. destill., 10 c.c.
S. One-fourth to one hypodermic syringeful to be injected beneath the skin over the sacrum. In children the initial dose should be 2 drops.—"Taschenbuch der Therapie."

**Treatment of Coryza in the Newborn.**—P. Rudaux, A. Grosse, and V. le Lorier recommend in the case of a simple coryza the instillation into each nostril, night and morning, of several drops of the following solution:

℞ Eucalyptol, 0.05 gram.
Sterilized liquid vaselin, 30 grams.

Menthol particularly should be avoided.

In the case of a syphilitic coryza the constitutional condition should be treated. In addition, there should be instilled into the nostrils three times a day four or five drops of a mixture of one part of hydrogen peroxide and four parts of sterilized water. Two hours later there should be instilled into each nostril several drops of the following:

℞ Resorcin, 0.25 gram.
Sterilized liquid vaselin, 30 grams.

If the act of sucking is embarrassed Laurens recommends the introduction into each nostril of three or four drops of a 1 to 10,000 solution of suprarenal extract.—"Clinique et Thérapeutique Obstétricales du Praticien."

**Therapeutic Value of Camphor.**—J. D. Heard and R. C. Brooks have performed a series of clinical experiments in which they found that camphor injected subcutaneously in oil in doses as large as 50 grains failed to produce any definite effects. The variations in pulse and in blood pressure occasionally following the use of the drug were so inconstant as to make it probable that they had no relation to the medication employed. The failure of the drug to influence clinical fibrillation of the auricle in the human subject is only in apparent contradiction with the authors' and other laboratory observations that perfusion of the isolated cat's heart with camphor may remove fibrillation and restore coördinate contractions. The explanation of this apparent discrepancy is probably to be found in the fact that the dose was greater in the perfusion experiments than was possible in the clinical observations, and that in the former the condition of fibrillation in the normal heart was induced artificially. A further point to be considered is that different animal species and varying ages even of the same species show marked differences with respect to fibrillation. In the single laboratory experiment in which a stimulating effect upon the circulation was observed, the positive result was possibly due to the fact that the animal was emaciated and moribund, and that therefore it may not have been possessed of sufficient glycuronic acid to combine with the camphor. Therefore, while camphor may be an active agent in certain disorders in which there is an abnormally small glycuronic acid content, and while experiments indicate that the drug exercises a favorable effect upon the heart muscle which is poisoned by chloral, muscarine, or strychnine, nevertheless the authors believe that camphor should neither be relied upon as a cardiac stimulant nor feared as a toxic agent in the doses employed by them and under the conditions studied.—*American Journal of the Medical Sciences,* February, 1913.

**The Treatment of Flatulence.**—Huchard recommends the following:

℞ Naphthol,
Magnesium carbonate,
Powdered charcoal, of each, 5 grams.
Peppermint or anise oil, 2 drops.

This is to be divided into 15 capsules, one of which is to be taken before each meal.

Neusser's prescription is as follows:

℞ Bismuth salicylate,
Calcined magnesia, compressed powder, of each, 0.1 gram.
Powdered rhubarb root, 0.05 gram.
Powdered charcoal, 0.15 gram.
Rectified English peppermint oil, 4 drops.
Gum arabic, q.s.

This should be made up in a pill coated with sugar and talc. Five to ten pills may be taken in the course of a day.

### THE RELATIVE VALUE OF LIVING AND DEAD TUBERCLE BACILLI AND OF THEIR ENDOTOXINS IN SOLUTION IN ACTIVE IMMUNIZATION AGAINST TUBERCULOSIS.

By KARL VON RUCK, M.D.,

ASHEVILLE, N. C.

While the value of any therapeutic or prophylactic procedure must, in the last instance, be determined by practical experience, it is nevertheless necessary to examine and to consider beforehand such evidence as may be available in order to guard us against disappointment and failure in the subsequent practical test.

Such an examination is all the more necessary when the procedure implies the use of bacteria and their toxins, and with them, as with the study of other poisonous substances, it has for a long time been customary to include experimental studies upon lower animals.

The attention which has recently been bestowed upon a claim of superior value of living though avirulent tubercle bacilli in the treatment of tuberculosis, has not been solely on the part of the general public or the popular press, if I may judge from the numerous requests for an expression of opinion which are coming to me from colleagues, who know that I have long been working on similar lines; and it is with a view of complying with additional requests for a more detailed exposition of the results of my studies and experimental inquiries as to the relative value of tubercle bacilli and their products for therapeutic and prophylactic purposes, that I have prepared the present paper, hoping at the same time that it may help others, not in a position to examine the subject personally, to arrive at an approximately correct opinion.

Products derived from tubercle bacilli in the form of the various tuberculins, and emulsions of their bodies have been in the hands of the profession for more than twenty years, and in hundreds of thousands of cases of tuberculosis they have been employed with more or less success, and not infrequently with failures while occasionally detrimental effects have been ascribed to their action.

Such an experience should not be surprising, when we bear in mind that in any case of demonstrable tuberculosis we are dealing with a disease in the course of the evolution of which important tissue alterations have already occurred, and that this is true even though we may in our clinical conception speak properly of an incipient or early stage, but by which we should mean clinical manifestations, rather than pathological states of the tissues involved.

Active immunization against an infectious disease, before it is contracted, may be a quite different proposition from that of active immunization after its clinical advent, and only in those which have a slow or chronic course, because the natural advent of protective or antagonistic reaction products is delayed, or because they are formed in insufficient quantities to bring about a spontaneous recovery, is the active method of value. Like in most chronic infections, so in tuberculosis, it is an active immunity against the life and the pathogenic action of the bacteria themselves which we seek to induce or augment.

I cannot here enter into details to show why it may be that there are many cases of tuberculosis which recover spontaneously, beyond stating that we assume that in such the necessary reaction to the specific bacillary substances occurs by reason of an increased sensitiveness on the part of the tissue cells, or it may be on account of their liberation and absorption in ample quantities, at a comparatively early stage of the disease. That such cases owe their recovery chiefly to the formation of specific protective bacteriolytic and germicidal substances we find support in the fact that these can be demonstrated in their sera by biological tests. Such a result is most frequent in that period of the disease in which there is as yet no evident destruction of tissue, or in instances in which the destructive lesion has been small and circumscribed. In either case we have reason to believe that bacillary products were absorbed into the circulation for but a limited period, or by a succession of such periods and that the intervals were long enough for the necessary reaction to occur. There are, however, many cases in which the resorption of the bacillary products is continued and massive, and others in which the simultaneous absorption of products from other pathogenic bacteria, associated and present in the destructive or ulcerative lesions, cause the organism to be overwhelmed and to prevent the necessary protective reaction, and so to say inhibit or suppress the formation of defensive antibodies. That this is the case can likewise be demonstrated by biological tests showing the presence of the related endotoxins or of the bacilli themselves in the blood for long periods of time, representing the so-called negative phase of Wright. The course of a given case depends, therefore, among other things, upon the resorption of products from disintegrating tubercle in which the endotoxins are present, and upon complicating associated infections with other bacteria, or both.

During the excessive or continued resorption of such products the specific protective antibodies, if present, and such as may form are chemically bound and united with the free endotoxins or bacilli in the circulation, and if we test such sera for amboceptor or lysis and demonstrate their presence,

it is not the actual amount produced, but only the excess which has not been bound. The endotoxins and tubercle bacilli which have thus united with the specific antibodies are disintegrated and their proteid substance is further reduced through the ferment-action of the complement. If this reduction is abrupt and massive, the organism is further endangered by the resulting reduction products which in small animals frequently cause their more or less rapid death from toxic shock. These reduction products are supposed to be toxic peptones, which are eliminated largely or entirely through the kidneys and account for the toxic action of the urine in tuberculosis as also in other bacterial diseases.

My observations and serum studies in the various clinical phases of pulmonary tuberculosis have supported me fully in the foregoing statements. They have further shown that with the advent of sufficient drainage and outward discharge a general amelioration occurs coinciding with the disappearance of the antigen (the endotoxin or the tubercle bacilli, or both) in the blood serum when tested against a standardized immune serum. The reappearance of bacteriolysis for tubercle bacilli may then be observed to occur, always slowly, reaching sometimes but small, at other times larger amounts, which stand in apparent relation, at least in part, with the nutrition of the patient and the rapidity of the improvement, but also with the state of the local lesions, their extent, and the continuance of complications. Not infrequently such an amelioration is followed by a reaccession of the excessive absorption of tubercle bacilli or of endotoxins, corresponding with renewal of tissue disintegration in the old or adjacent areas of softening or in a more distant locality.

Even with this concise statement of clinical observations the reader should have little difficulty in appreciating that active immunization is not always necessary, that if we resort to it at an inopportune period it will not only avail nothing but is liable to do harm, especially when the antigen is given in larger doses. He will also understand why it is that active progressive cases receive no, or but little, benefit from specific treatment, and why, on the other hand, I and others have observed such highly satisfactory results in that early clinical state of the disease in which tissue destruction is yet absent and in which no, or but very small amounts, of bacteriolytic and germicidal antibodies can be demonstrated in the patient's serum.

The results of my studies in more advanced cases give also a satisfactory explanation of the value of active immunization in instances in which, after tissue destruction and excavation, the active symptoms have subsided and in which we frequently fail to show a sufficient degree of immunity.

In the light of the observed fact that under any degree of immunity with or without apparent exciting causes, caseous and necrotic tissue, when present even though more or less encapsulated, may break down and thus lead to renewed absorption of bacillary products, we can likewise account for relapses, especially of advanced cases, and for the temporary or permanent loss of the previously present specific protective substances.

In external and other forms of localized tuberculous lesions of lymph-glands, bones and joints, and other parts, usually spoken of as surgical tuberculosis, my own observations correspond with those of others, that, as a rule, the advent of specific antibodies demonstrable in the serum occurs late or none at all are found, and that the massive absorption of endotoxins and tubercle bacilli from disintegrating caseous or necrotic foci rarely occurs, probably because on account of early peripheral lymphatic obstruction, or of earlier outward discharge, spontaneously or through surgical aid.

This class of cases is especially liable to derive benefit from active immunization, and the results are often brilliant and striking from a single large dose of the bacillary antigen, providing there is no necrosis or sequestrum of bone, and that any present products of disintegration of tuberculous tissue may have found a spontaneous exit, or providing that such exit has been secured surgically.

If we now proceed to the consideration of the method and of the antigen for the production or increase of active immunity, we may take it for granted that in tuberculosis we desire the antibacterial form, and with others we accept the fact that the body substances of the tubercle bacillus are necessary for its production.

The need of a certain interval between administrations for the gradual development and increase of the bacteriotropic and bacteriolytic substances, has been shown abundantly by Wright, these intervals depending on the size of the dose and being designed to afford time for the occurrence of the reaction by and through which these antibodies are formed.

As regards the particular form of the antigen there is one essential requirement, namely, it must represent all the body substances of the bacterium. In our case, then, of the bacillus of tuberculosis, and on account of the difficulties heretofore encountered even in their identification, to say nothing of their isolation in an uninjured and therefore active form, there have always been those who have insisted upon the use of the bodies of tubercle bacilli, dead or living, in order to assure the presence of all the endotoxins they contain, and the living form has been claimed by certain observers to be the most desirable, while there have been still others who held that virulence, either complete or attenuated, was likewise essential to success.

I cannot here cite the various authors who have advocated, upon one ground or other, one certain antigen as being superior to all others. The preparation of Robert Koch, known as Tuberculin R and his Bacillen Emulsion are examples of recognition of the need of all the bacillary endotoxins, and my own preparation which I gave out in 1897 under the name of Watery Extract of Tubercle Bacilli, and simultaneously with Koch's Tuberculin R, was prepared by me in like recognition and was supposed to represent the endotoxins freed from bacillary residue in solution.*

In the periods intervening to the present time these antigens have multiplied to such an extent that even a concise description of their preparation and claimed advantages would easily fill a small volume, but their value was urged chiefly upon results of clinical observations which, in the light of the pathology of tuberculosis and especially of phthisis, in the light of the occurrence of spontaneous immunity as mentioned heretofore, and in the further light of the fact that an untimely administration of

*Recent chemical studies of this preparation have shown that this is actually the case, even including the fatty extractives of tubercle bacilli which appear to be soluble in water. The relative proportion of the several bacillary constituents is, however, not such as to make this preparation fully efficient, there being an insufficiency of the nucleoprotein.

the most perfect antigen could fail or be even followed by harm, were necessarily contradictory, and their almost uniform failure in experimental use led some observers to take the position that a true immunity against tuberculosis had no existence in fact and was impossible of attainment.

All these questions are rapidly approaching a solution. The question whether or not true immunity could be produced against tuberculosis could be studied more accurately, clinically and experimentally, by the demonstration of specific antibacterial substances with the complement fixation test introduced by Bordet and Gengou in 1901, aided still further by its subsequent perfection by Wassermann and Bruck. Although the demonstration of a specific amboceptor gave no positive indication for actual protection or even for aid in the cure of tuberculosis, the admission has become general that the presence of specific antibodies and especially of amboceptor is at least indicative of an increased resistance, and gives support to the occasional successes of animal experiments.

As to the need of an antigen of living tubercle bacilli for prophylactic purposes, I may mention the introduction some years ago of "Bovo-vaccine" by von Behring and of "Tauruman" by Koch and Schütz for protective vaccination of young cattle. Both preparations represent living bacilli of human origin, as a rule but slightly or not at all virulent for that species of animals. For the value of endotoxins in solution and the necessity of the presence of certain fatty constituents of the tubercle bacillus, the critical, chemical, and experimental studies of Much and Leschke[1] may suffice to be cited.

Presuming that there will be no difference in opinion that a sterile, soluble vaccine, if equally efficient, is preferable for therapeutic as well as for prophylactic immunization to one that represents dead or living bacilli. I desire to call attention to the disadvantages that attach to the use especially of living tubercle bacilli for either purpose; some of which are also valid as regards bacilli that have been killed by heat, chemicals, or other methods of sterilization. Beginning with the least of them, we cannot determine with sufficient accuracy the content of the dose that we desire to give, a disadvantage which attaches to any emulsion or suspension, but which becomes greater with tubercle bacilli on account of their spontaneous clumping or agglutination. A further disadvantage, observed by all clinicians and experimenters who have used dead or living tubercle bacilli, is the liability to local necrosis and abscess at the point of injection, especially when larger doses are given, which support the view that the bacilli are absorbed, but slowly or not at all, at the point of their injection, and hence arose the necessity of adopting the intravenous method followed by von Behring and by Koch and Schütz, which, though itself no bar to the administration of a vaccine, is, nevertheless, a procedure requiring certain cautions and meets objections on the part of the individual to be treated.

Agreeing with others that in tuberculous subjects the power to disintegrate and thus to liberate the endotoxins of the tubercle bacillus, after its introduction dead or living, has been acquired by preceding liberations, however slight, of like endotoxins from degenerated or caseous tubercle in which the bacilli themselves have likewise degenerated or disintegrated, this power does not appear to be present in the normal animal and we therefore have no right to infer it in the nontuberculous subject when we desire to administer the antigen for prophylactic purposes; and in such subjects the evolution of immunity must be slow if it occurs at all, while likewise it is liable to be of slighter degree, unless all the bacilli have in time yielded their endotoxins. That this is the case I have demonstrated in 1896 and 1897 in the attempted immunization of a number of goats with an emulsion of living tubercle bacilli from an avirulent culture prepared in my laboratory. In none of these goats did I obtain an antitoxic or bactericidal immunity, but after killing them I found in their lungs and other organs enormous numbers of minute fibroid tubercle which microscopical examination showed to contain the unaltered tubercle bacilli, undoubtedly representing the antigen that had been injected in large doses and which had become encapsulated.

In subsequent and again in recent experiments I have further attempted the immunization of normal guinea pigs and rabbits with living and dead tubercle bacilli, with emulsions of my own and with that of Koch, and although I have succeeded after months of treatment, by the use of at first small and thereafter gradually increasing doses, in causing the formation of demonstrable quantities of specific amboceptors, I am still endeavoring to reach a degree of immunity sufficient to cause lytic power of their serum, or complement fixation with all of the several bacillary constituents. On the other hand I lost a number of such animals from degenerative processes in the liver and spleen when larger doses of the antigens were given subcutaneously, and local necrotic abscesses occurred in all instances, excepting when dead tubercle were used after their fats had been extracted. The intraperitoneal administration had to be given up because of fatal adhesive peritonitis which occurred even after a few and comparatively small doses. I conclude therefore that the normal organism of the lower animals, such as I have experimented with, has but little power to liberate the endotoxins from the bodies of tubercle bacilli and that it acquires this power only gradually, the same as is the case after epidemiological infection of the human subject, and I shall presume this to be the case in the nontuberculous human subject until the contrary has been shown. Like encapsulation has frequently been found in the tissues of cattle after the intravenous administration of bovo-vaccine and of tauruman and the varying degrees of immunity induced after their use may well be explained by the number of bacilli which became accessible or were eliminated or encapsulated in their tissues.

Inasmuch as living tubercle bacilli of the human type have been found in vaccinated cattle both in their tissues and in their milk, as long as three years after their intravenous injection, the objection to living tubercle bacilli as an antigen or vaccine for prophylactic purposes in the human subject is a valid one, and equally so for animals whose milk and flesh are used for human food.

A final and more formidable objection is, however, the danger of virulence. That this can recur in the case of tubercle bacilli the same as of other pathogenic bacteria is a well-known fact, and one or more passages of nonvirulent forms through susceptible animals is often ample to restore it. There are even those who claim success in causing reversion to a previous type, and an adaptation of virulence for animals for which the particular type was previously non-virulent.

A reduction in the degrees of virulence of laboratory cultures of tubercle bacilli is the common experience, and its entire loss for guinea pigs is not an infrequent observation. In the case of a human culture which had continued avirulent for seven years during my observation and which was avirulent when I received it, the virulence was reestablished after its recovery from a lymph gland in which no appreciable alterations beyond a certain degree of hyperplasia could be detected.

Passages of the mammalian or the avian type through ordinarily resistant, including cold-blooded animals, frequently cause an entire loss of virulence which is, however, not permanent. Thus Dubar found that he could adapt the human type to become pathogenic for fish, and was thereafter able to restore the virulence of the recovered culture for the guinea pig. The experiments of Auché and Hobbs,[2] Morey,[3] Sion,[4] Herr,[5] Dieudonné,[6] Weber and Taute,[7] Tsukiyama,[8] Jancso and Elfer,[9] Bertarelli and Bocchia,[10] and of many others with cold-blooded animals, including frogs, fish, blindworm, and turtle are relevant in the consideration of avirulence and of its more or less temporary character.

In now referring directly to Friedmann's claims[11] for the value of his living antigen in the form of tubercle bacilli recovered from a turtle, I take it that in the absence of contradiction on his part, in the discussion of his communication before the Berlin Medical Society, they are originally of the human type, according to the opinion of Piorkowski, who stated that he had isolated them himself in 1903, without in any manner questioning their non-virulence through the subcultures that must have been made since.

In the light, however, of the fact that many other creditable observers have noted the recurrence of virulence with like cultures it remains for Friedmann to show that his particular culture is permanently avirulent for the human subject, which he has, of course, not done, and which he is unable to do without resorting to the human experiment supported by autopsy. The test of avirulence for the guinea pig, while suggestive, is not conclusive and would not be, even if by passages through this or other animals, he had shown these to be resistant.

The ordinary duration of the life of a guinea pig is not long enough to show what might occur in the human subject, knowing as we do that an infection acquired in early childhood may not become manifest until in later periods of adult life.

We know that tubercle bacilli can continue, in a living state, in the tissues of animals without apparent pathogenic power for years, and we have ample evidence that this can be likewise the case in the human subject as shown by so-called latent infections, which after many years may become active and progressive. We must in the light of such observations conclude that though avirulent for long periods of time, the bacilli gradually adapt themselves to their host and acquire pathogenic power. To such a change the organism may itself contribute by metabolic changes in its own tissues, favored by intercurrent diseases, by trauma, or by nutritive disturbances, or the bacilli may acquire virulence by successive subculturing in the organism itself, *in situ* or after transport from a tissue highly resistant, to one that is less so.

It may, however, be presumed that Dr. Friedmann was in possession of ample and conclusive evidence to contradict at least most of the objections stated and others which might be suggested, before he inoculated several hundred infants and young children with his living bacilli, and that for their successful protection he will supply, in due time, other proof than the statement that "although some of them had been vaccinated a year before he made his communication, none gave evidence of scrofula." Valid evidence is the more necessary because none of the animals which he sought to protect with his living bacilli, resisted an infection with a but slightly virulent culture of tubercle bacilli, judging the degree of virulence by the length of time necessary to cause death of his control animals.

It being improbable that Friedmann will make the claim and supply proof that his bacilli have an associated action in the nature of causing complete sterilization of the tuberculous lesions by destruction of all other pathogenic bacteria that may be present, or that by other modes they act differently from all other tubercle bacilli in the production of a "cure," I take it that in the cases in which he has accomplished it, it was through the production of immunity, *i.e.* of bacteriolytic and germicidal antibodies, which developed in response to the administration of the antigen. If his special form of tubercle bacilli cause such a reaction, of which there need be no doubt, it is because of a correspondence in their receptor apparatus with that of the tubercle bacilli responsible for the disease, else there could have been no reaction and without such the injected bacilli would have represented nothing but foreign bodies, and would have undergone the same fate of removal or encapsulation, as did the foreign bodies in the form of cinabar, powdered hair, rubber, glass and the like, which were used in order to disprove Villemin in his classic experiments of many years ago.

Such a view is further justified in the experimental studies on the action of dead tubercle bacilli by Prudden and Hodenpyl,[12] Straus and Gamaleia,[13] Kraemer,[14] Panow,[15] Vissman,[16] Abel,[17] Delafield,[18] Auché and Hobbs',[19] myself and many others in which their fibroid encapsulation in the tissues of normal animals was the uniform result.

That an ample degree of immunity will result from even a single injection of living tubercle bacilli in *tuberculous* patients, especially if given intravenously, we need not doubt. We have, however, every reason to doubt that the results of such an immunity differ in any way from like degrees of immunity when induced more slowly, or with some other tubercle bacilli or antigens prepared from them, in the culturing of which there had been no passage through, or other relationship with a turtle.

The degrees of antibacterial immunity are not limitless and from other considerations it is perhaps fortunate that this is the case. It cannot be increased to degrees which have been shown possible in active antitoxic immunization, and when fully established against tuberculosis the serum of an immunized subject or animal has complete bacteriolytic power for the related bacilli and destroys their virulence. No further increase of specific amboceptors or lytic action appears thereafter to occur.

This then remains our measure by which we can determine the value of an antigen, and it would be gratifying if Dr. Friedmann had given some information on the results of his studies in this respect, instead of speaking only of uniform cures. Such information would likewise have made it impossible for Wolff-Eisner to oppose him in the

discussion of his paper on the ground of his work being lacking in scientific or even in a sufficient theoretical basis, and if he had likewise supplied it for the children which he vaccinated it would have saved him the strictures, which were made by competent men who seriously protested against his procedures in this respect, on account of lack of evidence of its value or its justification.

Whatever the individual conceptions of a cure of tuberculosis may be, and what Friedmann's own position in this respect is, matters little. We know full well that clinical cures are liable to be deceptive, not only in the advanced stage of phthisis, but even in external forms of tuberculous disease when apparent healing or cicatrization has occurred.

The meager information contained in Dr. Friedmann's professional communication of the nature, extent and forms of tuberculous diseases which he has cured, and the absence of statistical classification, usually supplied for clinical results, make their intelligent discussion or comparison with results obtained by others with specific or other remedies impossible. In this respect I hold, however, to what I have already stated in regard to the limitations of therapeutic immunization and of the benefits which it can confer, but I concede that in regard to the dose and mode of application of the "whole" antigen, Dr. Friedmann's method of intravenous administration may deserve further study, but with a degree of caution that will include the possibility of the development of more or less serious toxic symptoms in instances in which the injected antigen will meet with a highly lytic serum, as a result of spontaneous immunity which the patient might have acquired before; finding that we can thus kill our immunized laboratory animals, this caution is essential.

Coming now to the use of a non-living antigen in the form of the pure endotoxins of tubercle bacilli, I refer the reader to my preliminary announcement on May 1, 1912, of a practical method for prophylactic immunization against tuberculosis, especially in children,[20] and to my subsequent full report[21] in which I described my observations in greater detail. Without at all claiming that the vaccine there described was the only useful and practical one, I attributed its value to the presence of all the necessary constituents of the tubercle bacillus, obtained under precautions which assured the avoidance of their injury or modification. I have there also shown its safety and uniformity of action in producing a full and ample degree of immunity, so far as this can be at all demonstrated, and I described the mode of production of the vaccine in full details, enabling others to make a product identical with my own. I shall later refer to the nature of the proofs which I supplied.

About 300 additional children and adults have since been vaccinated and, as in the first series, their sera were examined for specific antibodies before and after the administration of the vaccine. Further animal experiments have been finished or are in progress, involving since May 1, 1912, the use of about 450 guinea pigs, over 50 rabbits and several calves and sheep, and upon the results of these continued observations I expect to report in detail when all the experimental work is completed.

The serum examinations and those of my animal experiments which are finished at the present time have given no materially different results from those reported last May, and none of the immunized and thereafter infected animals left over from my first series have given evidence of an existing infection. In the few animals which died from other causes their autopsy showed no evidence of tuberculous disease.

While I have so far abstained from the treatment of far advanced or otherwise unsuitable cases with my vaccine, and have not depended upon its administration in a single dose in otherwise suitable patients, in which the disease had advanced to a stage of tissue destruction, there were nevertheless a sufficient number of tuberculous subjects in my first series of cases and in those vaccinated since with a single dose, in which the results show that in the early stages of pulmonary tuberculosis a single dose appears to be ample to cause what may be termed a clinical recovery.

These cases may serve for eventual comparison of results, as concerns the early stage of pulmonary tuberculosis treated with a single dose when given subcutaneously and in case it should be shown that the intravenous method has advantages sufficient to consider it in the advanced stages of the disease, I have not the slightest doubt that, whatever these advantages may be, they will appear under the use of mine and of other whole vaccines, regardless of the absence of an associated history of the turtle or of another cold-blooded animal from the tubercle bacilli of which the antigens have been prepared. It is the method of administration of the antigen, the size of the dose, and the intervals between the doses, as practised by Dr. Friedmann, and not the derivation and nature of the antigen he uses, that may deserve consideration, in case it be shown that a larger per cent. of actual recoveries follow his method, in which according to nonprofessional sources he is not depending on a single dose. In my first report I have, however, also suggested that in my experience up to that time a few doses of my vaccine would suffice in the treatment of suitable cases, and I have since that time been able to confirm this further.

As to the therapeutic results observed I shall consider them in cases readily accessible to re-examination, in a semipublic institution where before and since they have been under the continued observation of Dr. C. A. Julian, the physician in charge. My observations in other cases, so far as I have been able to re-examine, correspond in all essentials with his. I quote from his report only such essentials as are relevant here, Dr. Julian expecting to publish his observations in greater detail himself.

The cases of interest comprise the tuberculous and probably tuberculous children vaccinated by me personally in 1911 with the assistance of Dr. Julian, and others whom he himself has vaccinated since. I deal with them separately because the results in the first series have been determined so long as fourteen months and in the second series only three months, after vaccinating.

Among the first series of 262 cases were 112 in whose physical and other examinations the evidence of tuberculosis was accepted as conclusive upon grounds of the usual diagnostic methods, including a positive reaction to a tuberculin test. In the 112 cases mentioned an extension of the disease to the lungs was shown by the presence of physical signs elicited by percussion and auscultation. In a large number of them the general condition was poor or unsatisfactory, catarrhal signs were frequently noted in the involved lung areas, a number of them

showed slighter degrees of fever, some had cough with or without expectoration, and in a few, tubercle bacilli had been found in their sputum.

Excepting seven cases in which, on account of the presence of evident destructive lesions in the lung or of other tuberculous complications, it was deemed prudent to administer the vaccine in small and increasing amounts, by giving from three to eight doses, there was noted last April a uniform radical change for the better in all respects, and I referred concisely to their improvement in my first report. Dr. Julian, who re-examined these cases last December, gives the following comparative increase in weight, fourteen months after their vaccination, for 109 between the ages of four and seventeen years, according as they were considered tuberculous, or only probably so, or had been found normal.

Tuberculous—Sixty-six cases; average gain 20 pounds; increase of body weight, 25.5 per cent.

Probably Tuberculous—Twenty cases; average gain, 13.8 pounds; increase in body weight, 24.2 per cent.

Normal—Twenty-three cases; average gain, 8.7 pounds; increase in body weight, 12.9 per cent.

To show the influence of vaccination in 112 cases upon physical signs in pulmonary involvements, the results of their preliminary examinations may be classed as follows:

| | Cases. |
|---|---|
| Signs marked in both lungs | 32 |
| Signs marked in one lung, slighter in the other lung | 28 |
| Signs of slighter degrees in both lungs. | 8 |
| Signs marked in one lung only | 22 |
| Signs slight in one lung only | 15 |
| Signs indicative of destructive lesions, or progressive | 7 |

As to his re-examinations after fourteen months, I quote verbatim from Dr. Julian as follows:

"The results of their physical examination made by me last December and therefore fourteen months after their vaccination corresponded in practically all the nonactive or so-called latent affections with those made last April, while in the cases classed as having destructive lesions in their lungs or otherwise pursuing an active course and in which marked amelioration and retrogression of physical signs had been found last April, the evidence to this effect is now more marked still.

"Excepting one case in which other than tuberculous disease accounts for an unsatisfactory state of health all these children are in excellent physical condition, those who apart from their lowered state of nutrition had also shown symptoms, like fever, cough, and expectoration have lost them at an early period and have remained free from them ever since. In twenty-seven cases in which the physical signs were of slighter degrees, nothing abnormal can now be shown either by percussion or auscultation. There is no evidence of apical catarrh in any case. In instances, however, in which the physical signs were marked, some degree of diminished resonance can still be shown in small and circumscribed areas over which the respiratory sounds are not perfectly normal, the inspiratory sound being either weaker or lacking in vesicular quality quantitatively, often with a harsh element coexisting or predominating. The other and adjacent parts which had previously given abnormal signs show no change from normal. In quite a number of these cases there is now more or less marked subclavicular retraction, corresponding with the area of diminished resonance and of abnormal respiration which in extent is very small, as a rule not exceeding 1 inch in diameter. I am therefore of the opinion that the present findings in all such cases are indicative of lesions which have undergone a process of healing and cicatrization corresponding as they do with signs generally accepted as of such import, and I am the more certain that this interpretation is the correct one, inasmuch as none of them have reacted either locally or generally to a subcutaneous tuberculin test which I applied about a month ago, whereas a like test applied before their vaccination was positive in every case in which it was made.

"Physically and clinically these children have all made a complete recovery after a single dose of the vaccine and with the one exception stated they are in perfect health."

Enlargement of lymph glands was found in eighty-four of the pulmonary and in eighty-two others, making a total of 166 cases. One or more of the cervical, axillary, or inguinal groups participated in the order named.

| | Cases. |
|---|---|
| One group only | 12 |
| Two groups | 97 |
| Three groups | 15 |
| Four groups | 38 |
| Five groups | 2 |
| Six groups | 2 |

Re-examination after fourteen months gave the following results:

| | Cases. |
|---|---|
| Not examined | 6 |
| No enlarged glands in any group | 153 |
| Enlargement found of one or two groups | 7 |

The difference in body weight three months after vaccination in 110 cases of the second series are as follows:

Tuberculous—Thirty-six cases; average gain, 10.1 pounds; average increase, 16.1 per cent.

Probably Tuberculous—Forty-eight cases; average gain, 13.8 pounds; average increase, 13.9 per cent.

Normal—Twenty-six cases; average gain, 3.6 pounds; average increase, 4.3 per cent.

In regard to physical signs on the part of the lungs there were thirty-one among the tuberculous, as a rule children between the ages of twelve and sixteen years, who presented evidence of lung involvement. In twenty-six the lesions corresponded with an early stage. In five children the lung affection was more advanced.

| | Cases. |
|---|---|
| Signs marked in both lungs | 2 |
| Signs marked in one lung, slighter in degree in the other | 8 |
| Signs slighter in degree in both lungs. | 2 |
| Signs marked on one side only | 12 |
| Signs slight on one side only | 2 |
| Signs indicative of destructive lesions. | 5 |

I again quote from Dr. Julian as to his findings three months later as follows:

"The result of my re-examinations made three months after vaccination show that in ten cases all physical signs have disappeared and in instances in which slighter signs indicated an extension to the

opposite side, these have also disappeared. In all the remainder excepting two of the advanced cases, which are still under treatment and are also much improved, the physical signs have almost completely disappeared being now limited to very small areas; in cases in which catarrhal signs were previously recorded these have disappeared. The respiratory sounds in these circumscribed localities are rather weak or lack in the unmixed vesicular element, while the percussion note is not as fully resonant as it is on the opposite side. All previously present symptoms have disappeared, the temperature is normal in all, and the general condition of nutrition, strength and sense of well-being is good.

"A tuberculin test, previously positive in all cases classed as tuberculous or suspected to be so, and made again in January, is still positive in six cases, three of them, having previously shown physical signs and slight subjective symptoms, were vaccinated with a single dose, the fourth case had been further treated and has since been dismissed, and the other two cases are still under treatment."

In regard to enlarged lymph gland, such were found in eight of the pulmonary cases and in thirty-two of the tuberculous or probably tuberculous classes, making a total of forty cases and involving:

| | Cases. |
|---|---|
| One group | 2 |
| Two groups | 31 |
| Four groups | 5 |
| Six groups | 2 |

Of the results of his re-examinations Dr. Julian states that he has been unable to find glandular enlargement in any of the cases after a most thorough search.

I have heretofore stated that my observations upon children and adults vaccinated in Asheville with a single dose or with several small doses in whose cases I have had an opportunity for re-examination gave practically the same result.

In all of Dr. Julian's cases as well as in those re-examined in Asheville, the sera were again examined and the examinations were repeated until the specimen showed the proper coincidence in complement fixation, as explained in my first report, sufficient to show an unmistakable lytic action upon virulent tubercle bacilli *in vitro*. It was not always possible to continue these examinations long enough on successive days to show complete disintegration of tubercle bacilli to the granular state, but when this could not be shown in the first or second test, it was always possible to do so when the examinations were continued further.

So far as animals could be spared, the bacteriolytic test was controlled for destruction of virulence before and after the administration of the vaccine, and since May 1st over 100 animals have been used for this purpose in new cases and in re-examinations of others vaccinated in 1911.

Concerning the evidence available at this time, I can anticipate my next full report with the statement that I have as yet not been able to note the complete destruction of virulence or a marked degree of bacteriolysis *in vitro*, with sera taken before vaccination, or from untreated patients, although a marked difference is evident in the duration of life of the animals in favor of sera which show a trace of lysis *in vitro*.

This difference I am able to overcome, in part at least, by using a highly virulent culture of tubercle bacilli, which kills the control animals between the twentieth and twenty-fifth day, and with this culture I find that the lysis *in vitro* must be complete to prevent the development of tuberculosis in animals infected with the residue of the lytic tube. For assurance of the complete resistance of immunized animals to infection with the culture spoken of, I likewise find that their immunization must be carried further than appeared necessary with the culture used in my first series of experiments, which required twice the time, *i.e.* six to seven weeks, to kill the controls. To know beforehand that this degree of immunity is present or that the animal will surely resist, its serum must first be tested for its lytic action and a degree of complete disintegration of the bacilli must be in evidence.

In closing, I believe that I have the concurrence of all students of immunity in tuberculosis, that with the evidence now before us there is no apparent advantage to be expected from the antigen for which Friedmann has made his remarkable therapeutic claims.

That a vaccine such as I have described, consisting of the extractives of tubercle bacilli in suitable combination and proportions, representing all the endotoxins essential for active immunization, is ample and sufficient, I believe I have supplied good evidence in its prophylactic, as well as in its curative aspects, and I am at a loss to know how it could be augmented or made more conclusive than it is, and I summarize this evidence as follows:

1. That after the administration of a single full dose of the vaccine all the specific antibodies including the several amboceptors can be demonstrated in the blood serum of every case, with the whole and with all partial antigens, after the fourth or fifth day, and that these antibodies suffer no quantitative diminution for periods up to twenty months.

2. That, under proper coincidence of complement fixation with the several partial antigens, such sera have a maximum bacteriolytic power *in vitro* sufficient to cause complete disintegration of the bodies of virulent tubercle bacilli to a state of granules and free fats; and *in vivo* to cause their complete destruction to a degree that after twelve to twenty-four hours no bacillary residue is demonstrable under any method of staining.

3. That the sera completely destroy all virulence of the bacillary residue left over in the tubes used for bacteriolytic tests *in vitro*, and that properly immunized animals withstand the test *in vivo* as do also normal animals when a proper amount of the immune serum is injected at the time when the infection is made with virulent tubercle bacilli or when the latter have been exposed to its action.

4. That animals can also be immunized to a like degree, their sera showing the same bacteriolytic and germicidal action *in vitro* and *in vivo*, and that the immunized animals resist completely a virulent infection, quantitatively many times greater than is necessary to invariably kill the control animals.

5. That in over 150 cases representing the early stage of pulmonary tuberculosis a single full dose was invariably followed by what may be termed a clinical cure.

In my previous publications I have supplied all necessary proof in justification of the foregoing conclusions, excepting for the curative effect, for which I then felt that further observations were necessary for making a claim other than that the cases were improved.

The results of re-examinations made since, and the continued correspondence of further observations in equally large number of vaccinations and in much more numerous animal experiments up to the present time, make it improbable that these conclusions will require essential modifications in the future or in my next full report, to be made when the outcome of some experiments still pending can be definitely determined.

## RADICAL AND CONSERVATIVE METHODS IN OBSTETRIC TREATMENT.*

By GEORGE W. KOSMAK, M.D.,

NEW YORK,

ATTENDING SURGEON, LYING-IN HOSPITAL.

When your chairman invited me to read a paper of not over twenty minutes' duration on some practical subject it was quite natural that I should choose a topic which personal experience had impressed me as of importance and upon which I could therefore presume to speak with some slight degree of assurance. Some of the views about to be stated are entirely personal, although largely based on results obtained in the service of the Lying-In Hospital.

In the advances which have been made in medical art and science during recent years, radical therapeutic tendencies have become very manifest. This is true in obstetrics as in other branches of medicine, and we often find the purely obstetrical methods superseded by those which are characterized by an undoubted surgical tendency. For many years obstetrics was considered a branch of medicine rather than of surgery, a branch which was relegated to the background as one of those adjuncts of medicine which had to be practised as a matter of necessity rather than of choice. In fact, it is only within comparatively recent years that operative obstetrics has assumed the importance which it deserves, and the brilliant results obtained have attracted the interest and services of many men whose inclinations are surgical rather than medical. This is in many respects an unfortunate tendency, as it has often resulted in a desire for greater haste in the conduct of a delivery, and has often been productive of doubtful judgment in the numerous complications attendant upon pregnancy, labor, and the puerperium.

*Read before the Bronx Medical Association, January 8, 1913.

It is my purpose this evening to discuss briefly some of the commoner obstetrical procedures, from both the conservative and radical standpoints, although it must be admitted that the matter is too extended and important to be more than superficially referred to in a limited paper of this kind.

To be prepared is to be forewarned and nowhere is that better shown than in the diagnosis of the details of a pregnancy and an exact knowledge of the prognostic features in every individual case.

Let us begin, therefore, with certain essentials in the examination of pregnancy in its earlier stages. It is here that I would urge a radical view in contrast to what ordinarily obtains among patients, and, it is to be regretted, among many physicians.

A woman should place herself under the care of a physician as soon as pregnancy is suspected, and at this first interview her previous general history should be gone into, supplemented by as extended a physical examination as may be deemed essential. There are several conditions which present themselves at this time that need to be mentioned if only for the purpose of calling attention to the necessity for exercising greater care in their conduct.

The ordinary nausea and vomiting of the early months of pregnancy must be carefully differentiated from the extreme and pernicious variety. We know enough about the latter to attribute it to a toxic basis and its treatment therefore should be founded on comparatively radical lines, including absolute rest and quiet for the patient, stimulation of the emunctories, complete withdrawal of mouth feeding and the substitution of nutrient enemeta, careful urinary analysis with special attention to quantity, specific gravity, and the tests for acetone, indican, diacetic, and oxybutyric acids; and finally the induction of abortion, when necessary, before the patient gets too weak to withstand the shock which usually attends even this operation in a woman exhausted by continuous vomiting and the attendant starvation and toxemia.

The treatment outlined may be called radical and stands in sharp contrast to that dependent upon the administration of a variety of sedative and other drugs, together with continued but usually futile attempts at mouth feeding. On the other hand, if associated with such vomiting we find a displaced and perhaps incarcerated uterus, this must be restored and held in position by a pessary.

The differential diagnosis between intra- and extrauterine pregnancy, when called for by the intervening symptoms, is of greatest importance, and in the presence of the latter condition no palliative measures should be tried but resort had at once to a radical operation, as the possibility of rupture with fatal hemorrhage is always imminent. If rupture has already taken place there is only one variety, the intraligamentous, which might obviate immediate operation, but even this is usually so uncertain

in diagnosis that palliative or conservative measures are of doubtful value.

Our attitude, whether conservative or radical, in the presence of an abortion, must depend entirely on the particular case in hand. In the threatened variety conservatism is the rule—rest, sedatives, etc.,—but in the incomplete type a more radical stand is necessary. In my personal contact with a considerable number of cases of miscarriage in private practice, and a very much larger number in the service of the Lying-In Hospital, I have seen but three complete extrusions of the early ovum. It is rare that the products of conception are entirely eliminated from the uterus, and this means that the retention of a portion of the same is likely to lead to trouble. A radical treatment is therefore indicated, which I merely desire to refer to as consisting of a thorough curettage of the uterine cavity, conducted under the most careful aseptic and technical auspices in every incomplete case, except in the presence of evident septic infection. The good results of this radical method of treatment are well demonstrated by the favorable mortality and morbidity statistics in 3500 abortion cases from the Lying-In Hospital service, recently collected by Ross McPherson (*Bulletin of the Lying-In Hospital,* Vol. viii, No. 4), in which 85 per cent. of the total number required curettage for retained secundines.

Taking up next a feature of pregnancy which does not usually meet with sufficient consideration, I desire to call attention to the necessity of making a complete abdominal and vaginal examination of every pregnant woman between the seventh and eighth month, for the purpose of determining whether any pelvic dystocia is likely to interfere with the labor. This should be done even in multiparæ with a history of previous normal labors. It necessitates careful external and internal pelvic measurements, and in no instance, either in private or hospital practice, have I found any objection on the part of the patients if the purposes of the same were explained to them. It is extremely important to recognize a contracted or otherwise deformed pelvis before labor, as a favorable outcome depends on the institution of proper measures at as early a date as possible. We must estimate not only the true conjugate diameter of the pelvic inlet, but also obtain a definite idea as to the presence of any lateral contraction or a diminution of the diameters of the outlet. In a great many cases the anteroposterior diameter at the brim will be found to measure ten centimeters and over, whereas there may be a considerable flattening from side to side or a marked narrowing of the pubic arch. The former will prevent engagement of the head except in the case of a small child, and the latter, if unrecognized, may delay delivery for many hours, with final death of the fetus and the production of extensive lacerations of the maternal soft parts. In the presence of these deformities, as well as in the generally contracted varieties of a minor degree, the so-called borderline cases, it is necessary to use the greatest skill and judgment in determining the proper course of procedure. In view of the possibility of a spontaneous labor in the face of obstructions on the part of the mother, a conservative attitude may seem desirable, and yet in how many cases do we find after an exhausting labor of many hours that very little advancement has taken place and the condition of the patient and the baby demands a hurried delivery? Pituitrin has been favorably spoken of in such cases, but in my own somewhat limited experience I have not been sufficiently impressed by this preparation to place much reliance upon it in the particular class of cases noted. It would seem advisable, therefore, not to depend too long on the natural forces for a satisfactory completion of the labor under such circumstances.

The immediate variety of delivery to be adopted depends somewhat on the conditions at hand. With a head firmly engaged in the brim and no progress after several hours of good pains, when a period of rest secured by morphine fails to strengthen the uterine contractions, then a high forceps extraction may serve our purpose. We should proceed very cautiously, however, before doing the same, and we must be certain of our technical ability in such cases.

The only instrument which is really safe in this particular condition is the Tarnier axis traction forceps, and in making an application of the same we must be particularly careful in our diagnosis of position, so that the application may be made most advantageously for the child. Brute force should never be exerted in such traction efforts, and the pull must be directly with the forearms of the operator, rather than with the trunk and the legs braced up against the operating table or the bed. If this or any other forceps extraction is resorted to a patient should always be placed on a table and the legs held by assistants or by a leg holder, the precaution having previously been taken to anesthetize the patient before putting her into the lithotomy position.

We are sometimes misled in such cases as to the "moldability" of the fetal head, and should not therefore persist too long in our efforts at extraction by this means. A dead child is only too often the result. Conservatism should in such cases always give way to a more radical attitude, where the circumstances demand the same, and this change should not be delayed so long that the chances of life for the child are greatly diminished. Where we have a moderate degree of pelvic contraction, particularly if this involves the outlet, and a living child with a large head is present, the operation of pubiotomy offers the best chance for a living child without endangering the life of the mother to any great extent. In making this statement I admit that such a procedure under these circumstances should not be resorted to without deliberation, but if we have given the woman every other chance and a living child is still present, it is preferable to resort to this operation rather than sacrifice the child to a craniotomy. The details of the operation for dividing the pubic bone I need not go into here, but the experiences of recent years seem to favor greatly an increased employment of the procedure. It is particularly applicable in those cases where there is a history of very difficult previous labors, with the production of stillbirths or fractured fetal skulls, and in protracted cases the chances of a dangerous or fatal septic infection for the mother, especially if numerous vaginal examinations have been made, is greatly reduced.

In the presence of a flat pelvis with poor engagement of the head, particularly in a multipara with a relaxed uterus, the production of an internal version, carefully done, will often result in a successful delivery, whereas a waiting policy may have resulted disastrously for both mother and child. I might refer in this connection to a series of ten

internal versions done during one of my recent periods of service in the Lying-In Hospital, with only one fetal death and that due to a prolapsed cord. Although somewhat radical, I believe that in cases of slight pelvic contraction, particularly in multiparæ, internal podalic version offers a better chance than the high forceps, as it is readily carried out and less danger of producing injury to the fetal head is probable. It is acknowledged that fractures of the clavicle or humerus are not unusual or unimportant in these cases, but they are readily treated and less dangerous than fractures in the cranial bones produced by the application of the forceps. I do not advocate a general adherence to this procedure in cases where the true conjugate measures less than 8½ or 9 centimeters, or in primiparæ, particularly if during the preliminary examination under an anesthetic it was determined that the head was too large to engage. In such cases an abdominal cesarean section, if performed early enough, would certainly afford the woman and child a better chance than either forceps or version.

The operation of pubiotomy in connection with these cases I have already referred to. Where a tonic contraction of the uterus is present, however, we must proceed with great caution in doing a version, and I have met with several cases of rupture of the uterus as the result of version done by men who have not been careful in formulating their indications before doing the operation.

In the matters referred to in the last few paragraphs a radical rather than a conservative attitude is urged, but here as elsewhere, care and good judgment is indicated, with a capacity for doing the particular procedure demanded.

Another subject which demands our most careful decision regarding conservative or radical treatment is that of the toxemia of the later months of pregnancy, ordinarily known as eclampsia. It is here that at the present time the profession is still very undecided as to what course to pursue. We meet with the most extreme views on both the conservative and radical sides. A prominent American operator, Reuben Peterson, advocates cesarean section, either vaginal or abdominal, in every case of eclampsia where a convulsion is present. The other extreme stand is that taken by the well-known Strogonoff of St. Petersburg, who relies entirely on sedative measures to overcome this dangerous condition. Both schools have been able to bring forward very plausible theories and statistics to support their claims, yet it would appear as if an attitude which occupies a middle ground between the two extremes, with a tendency toward conservatism, will in the future show the best results.

The most recent contribution to the subject as to whether we shall employ active or expectant treatment in eclampsia, is that published by Lichtenstein of Zweifel's Clinic in Leipsig, in which since April, 1911, the expectant treatment for this condition has been followed. Venesection with the abstraction of not less than 500 c.c. of blood, combined with Strogonoff's sedative measures, were employed, and out of a series of eighty eclampsia cases there were five deaths (6.25 per cent.), although one of these patients died of peritonitis after attempts at forceps extraction, and two of inspiration pneumonia. Out of sixty-four viable children, thirteen died (20.6 per cent.) in contrast to 36 per cent. during the period of active therapy. During the last twelve months in which the conservative treatment was employed not a single eclamptic mother died in a series of sixty consecutive cases. In forty-seven cases out of this series the convulsions ceased as soon as the venesection was done and spontaneous labor occurred in fifty-three cases (66.3 per cent.) with the conservative treatment, in contrast to 22 per cent. with the other. Similarly favorable results are reported by Engelmann from the Dortmund Clinic.

Delivery by vaginal cesarean section is undoubtedly a very rapid method of extracting a living child, but ought we to be satisfied with such a procedure in view of the fact that eclampsia often comes on before term and that therefore the child frequently perishes within a short time after delivery, as it is poisoned by the same toxins which have affected the mother? It would seem advisable therefore that the radical treatment of this condition be modified and a middle course pursued, which means a combination of sedative and eliminatory measures with a resort when necessary to delivery by those methods which will do least to increase the shock to the mother. In most instances, however, we can disregard the life of the child for the reasons already stated. Delivery by gradual dilatation would seem preferable in most cases therefore to the more extreme operative measures.

I may in this connection quote a case which occurred recently in my own experience. A young primapara, not quite seven months along, had several severe eclamptic seizures when brought to the Lying-In Hospital. There was no dilatation present. The patient was given morphine and chloral and twelve ounces of blood were abstracted from a vein in the arm. Clearing out the fecal matter from the rectum by enemata, followed by irrigations with normal sugar solution, hot packs, several doses of nitroglycerin, rest in a quiet room and no further examinations, were included in the method of treating this particular case. No further convulsions occurred after the venesection, the blood pressure subsided gradually, the patient perspired freely, the urinary secretion increased, and within a few days the woman seemed perfectly well. She was carefully watched and within two weeks delivered herself spontaneously of a dead baby.

What would we have gained in this case by the performance of a vaginal cesarean section or a resort to an *accouchement forcé?* We would have been favored with a small baby that probably would have perished within a short time after its birth and the mother unnecessarily exposed to a severe operative procedure. Vaginal section in such cases has repeatedly been found not to be the simple operation which many of its enthusiastic adherents would have us believe.

A final obstetrical condition to which I desire to direct your attention, in which the choice of radical or conservative measures is most important, is that of puerperal sepsis. Prophylactic measures to guard against this complication are so well known that it is needless to refer to them here, but notwithstanding this general knowledge puerperal sepsis is unfortunately all too common. The question as to whether or not it is always due to the doctor has not been fully settled, and recent investigations seem to show that in a certain number of cases we are dealing with an endogenous process. There is nothing which demands greater care and judgment than the proper handling of cases of pueperal infection. In the first place we must be careful in attributing a rise of temperature during the puerperium to its proper source; the bowels, the breasts and other organs must be eliminated in every in-

stance before referring this to the genital tract. An instance of infection during the puerperium is usually productive of much worry on the part of the attending physician, and in view of this he is very likely to resort to unnecessarily radical measures in its treatment. Nowhere is this better expressed than in the desire for making an intrauterine examination with the possible employment of intrauterine douches, and I have repeatedly observed cases both in private practice and in the hospital where a patient's chances for a rapid recovery were very greatly invalidated by the institution of such radical methods of treatment. In our service at the Lying-In Hospital, where we naturally come in contact with a great many cases of puerperal sepsis which are sent in by outside physicians or midwives, we have had excellent results with a most conservative method of treatment, which I will briefly outline.

A woman who develops a temperature which cannot be traced to any other source, who presents a profuse and foul lochia, or even a scant discharge, associated with distention, abdominal tenderness, headache, coated tongue, and the other well-known symptoms of puerperal sepsis, is kept in bed, the head of which is elevated for the purpose of securing better drainage both from the uterine canal and the vagina. The bowels are cleared out with a dose of castor oil or calomel and the patient put on liquid diet. In order to limit the absorption of septic material from the uterus, contractions of the latter are secured by the administration of small doses of ergot and the application of an ice coil in the lower abdomen. A cleansing vaginal douche is sometimes given, but no intrauterine manipulations are resorted to except in the presence of some particular indication. For example, if an examination shows the presence of a sharply flexed uterine canal that causes retention of the lochia, this may be dilated with the finger in order to secure a better discharge of the secretions; but intrauterine douches and packing are not resorted to as a general rule. If lacerations or stitch abscesses are present these, of course, are treated antiseptically. We have tried various sera, but with doubtful success, and in following this conservative method of treating our puerperal septic cases have been singularly favored with good results. Later on if pelvic exudates are present the women are likewise treated along the same lines, no operative interference being resorted to unless distinct abscesses are present.

In conclusion, there are a few points in the treatment of the new-born child to which I would like to call your attention. In my opinion resuscitation of the newly born infant is often conducted along lines that are entirely too radical, especially if the mother has been subjected to some operative procedure. Forcible slapping, bending and swinging, removal of mucus from the respiratory passages with dry gauze sponges, etc., need not be resorted to as a routine procedure; they are very often productive of irreparable damage to the child, which can be much more effectively resuscitated by stimulating the action of its chest muscles by means of artificial respiration, and hot and cold tubs. In the presence of depressed fractures of the skull in the new-born, produced by the forceps or the sacral promonotory, an immediate elevation seems preferable to following a waiting policy, as we never know in these cases what permanent damage may result to the child's head by leaving this deformity without treatment. It is a very simple matter with a proper instrument to lift the depressed fragments of bone without danger to the child and then we can be sure of comparative freedom from future complications.

There are many other aspects in this important question, namely, whether we should follow a radical or a conservative method in treating obstetrical conditions, which I cannot take up within the limits of this brief paper. I hope to have shown, however, that we must be prepared to take a stand on either side, depending on the particular indications in the individual cases. Extreme conservative or radical measures must not be insisted upon, and care, deliberation and good judgment invariably exercised before deciding on the method of treatment. Insistence on one line of attack is also to be deplored, and the obstetrician should always be ready to swing over from one line of treatment to another if the indications demand the same. In obstetrics perhaps more than in any other branch of medicine quick judgment is desirable, but this should always be governed by expediency and experience, and not according to the rule of thumb.

23 East Ninety-third Street.

## THE TREATMENT OF LIME STARVATION.

By JOHN F. RUSSELL, M.D.,

NEW YORK.

Rickets, tuberculosis, scurvy (infantile and adult), and many disorders accompanying pregnancy and lactation, may all be traced to lime starvation. My experience in the treatment of these diseases is restricted almost wholly to tuberculosis, the exception being a few cases of rachitic children and a few pregnancies. This restriction explains the prominence given in these pages to the dispensary curative treatment of tuberculosis in the work of which I have had large experience and which I regard as of first importance among the measures for the ultimate control of the disease.

The successful management of the tuberculous requires confidence, firmness, and that familiarity with detail commonly called skill. The physician is a leader and a necessary quality of a leader is confidence. Confidence arises from conviction, and conviction and skill are both acquired by observation and study. Discipline is necessary in the treatment of the tuberculous, and discipline calls for firmness. Every now and again patients appear who rebel at discipline, to whom routine is irksome, and who, for a time, attempt various infractions of the rules. The management of such cases becomes a kind of benevolent persecution which in the majority of instances ends quickly and happily.

In other words, for those who desire to practise the treatment described in the following pages, the best course to pursue is to come to the Thompson street rooms, and study the patients and their management long enough to reach a decision as to the value of the method, as well as to gain the necessary skill in conducting the treatment to a successful conclusion. That this is the wisest plan there can be no doubt, but so many physicians who wish to employ the treatment write that they cannot come to New York and follow the plan suggested, and yet ask for details, that I have decided to publish this paper with the hope that it will be of some service and possibly in the end lead to a closer study of the treatment and its application to the diseases other than tuberculosis which are primarily due to lime starvation.

The theory upon which the treatment is based is briefly as follows:

The necessity for lime in the food of animals and plants has long been recognized. Without this element both plants and animals sicken, and, if the poverty continues unrelieved, develop diseases which finally produce death. The farmer ordinarily supplies his land with inorganic lime salts, but has learned that to obtain the best results phosphate of lime in organic combination must be employed. He uses bone meal for this purpose. Hens are furnished oyster shells ordinarily, but if ground green bone is added to their food egg-laying is greatly increased. Physicians, on the other hand, have attempted to relieve lime starvation, rickets, and the anemia of nursing women, for instance, by the administration of mechanical mixtures of lime salts. It is but simple justice to admit that the farmer has succeeded better in meeting his obligations than the physician. The reason for this is clear. The farmer's problem is to supply necessary food alone. He can rely upon the ability of healthy plants and animals to assimilate it. The physician ministers to subjects whose food may contain an abundance of lime, but who have lost the power to render it assimilable.

Lime salts appear to be of special physiological importance. The formation of cells, the clotting of blood and milk, nervous and muscular equilibrium, depend upon their presence. Phosphate of lime forms a part of the normal structure of every organ in the body. Lime is being constantly discharged from the body as physiological waste material. It is, therefore, an essential plastic element of food. Three results must then follow an insufficient supply of lime: (1) Imperfectly developed organs; (2) lowered resistance to disease; (3) lack of power to repair physiological waste; lack of power to repair injury. Imperfect structure of an organ leads to impaired function. Resistance to disease is a physiological function, therefore, imperfect organs must exercise imperfect resistance. Growth and repair are dependent upon cell formation. Cell formation will not take place in the absence of lime phosphate. If there is a deficiency of lime phosphate and disease has already been established, its extension is unobstructed because no plastic effusion is possible in the absence of lime phosphate. Injuries are healed by plastic effusion, and phosphate of lime is the element which makes such effusions plastic. Lime does not act as a poison to the bacillus in the treatment of tuberculosis, but serves to restore the normal protective function of the cells in producing a fibrosis, the result of plastic effusion, at the point of irritation caused by the growth of the bacillus.

Certain preliminary changes are necessary before lime phosphate is ready for absorption by the tissues. Everybody understands that protein, starches, and sugars must first be changed by digestion before they can take part in physiological processes. So it is with phosphate of lime. It must first be combined, and after this digested. Even should this salt reach the blood unchanged and circulate as an inorganic salt, it is useless in this state as building material, and would be discharged. To be utilized by the tissues as food it has been found that lime phosphate must be presented to them in chemical union with protein. The presence of many of the mineral salts is necessary for the performance of physiological acts merely in order to give the particular reaction, acid, alkaline, or neutral, without which the acts cannot take place. The function of phospate of lime is much higher, and preparation is required before its purpose can be achieved. For here is an inorganic, inert material which is to be incorporated into and become a part of living matter. A stone is to be endowed with the attribute of life.

It has been discovered further that nature has provided an enzyme in the stomach, the action of which combines lime phosphate with casein, viz., rennet. The clot produced by rennet in milk is caseate of lime, a chemical union of lime with protein. Normally this is the first change produced in milk when it reaches the stomach. The combination is further acted upon by pepsin and finally absorbed in a form suitable for assimilation by the tissues. Lime phosphate in the blood serum is found in combination with albumin, and circulates as lime albuminate. Two things are essential, therefore, that the body may receive its necessary supply of phosphate of lime, viz.: First, a supply of suitable food; second, the action of rennet. In the majority of cases of lime starvation the food previously eaten has been suitable, so that the commonest cause of the trouble must be absence of the active ferment. This brings us to a consideration of rennet and the causes which interfere with its presence in the stomach.

Rennet occurs in the stomach either in an active free state (as in calves and sheep), or in the form of an inactive zymogen which is transformed by acids into the active form. In man it occurs in the form of zymogen. Its presence is never wanting in sucklings. The formation of the ferment from the zymogen is entirely dependent on the presence of free acids, so that in the absence of the latter from the gastric juice the free ferment is invariably wanting, even though the zymogen is present. Almost all acids may be used for converting zymogen into the active ferment. The best is hydrochloric acid; the least effective, acetic acid. In the stomach lactic acid and other organic acids also act as zymoplastic agents, in the absence of hydrochloric acid. Rennet zymogen is never absent from the stomach of man, even in pathological conditions, unless the secreting glands are destroyed, as in carcinoma. It is evident, therefore, that insufficiency of free acid is the cause of deficiency of free rennet in the stomach. So, in the last analysis, the presence of acid in the gastric secretion is the factor which brings about the combination of lime and proteid.

Attention is directed to the fact that rennet and pepsin zymogen are never absent from the stomach, either in health or disease, so long as the glands have not been destroyed. It is obvious, therefore, that the administration of either rennet or pepsin is wholly unnecessary under any circumstances except possibly the later stages of gastric carcinoma. The administration of acid is all that is necessary to produce the active ferment.

While it has not been demonstrated that proteins other than casein are combined with lime by the action of rennet, all analogy points to such combinations as certain. Rennet is found in muscle, liver, blood clot, and testicles. The gizzard of fowl, the stomach of fish, different parts of many plants and flowers, contain rennet. Its presence in all these situations points to a wider range of usefulness than would be the case if casein alone was the only protein which it could combine with lime. The gizzard of chickens is particularly rich in rennet. Milk forms no part of the natural food of

these fowl, and yet their demand for lime for egg shells is enormous during the laying season. The daily need of lime for human adult males is comparatively small, though even this small amount is essential for health. There are many perfectly healthy adults who rarely if ever drink milk. In these instances protein other than casein must be combined with lime.

The acid of the stomach, in addition to the activation of the stomach enzymes, has another important function. It has been found that the secretion of pancreatic fluid is started by a hormone secretion, which is itself developed by the action of the acid from the stomach, after it escapes from the pylorus, upon the upper part of the duodenum.

Many conditions of ill health check the secretion of hydrochloric acid in the stomach. The commonest are fever and gastrointestinal diseases. The secretion may be entirely checked, or it may only be diminished. A diminished secretion is probably the usual fault in cases which finally end in tuberculosis. In the majority of instances lime starvation is brought about slowly. The explanation being that if the diminished amount of hydrochloric acid is not entirely neutralized by the salts of the food eaten, and if the diet contain, in addition to lime-bearing foods, organic acid enough to bring about the combination of a small though still insufficient quantity of lime, evident symptoms of lime starvation will be delayed for a long time. The exacerbations and remissions observed in the course of tuberculosis are accounted for in much the same way. The remissions are due to some change of diet by which it includes lime-bearing foods and sufficient organic acid to insure the combination of lime with protein. The exacerbations, on the other hand, point to the absence of either the one or the other, or both. During prolonged fevers the secretion of hydrochloric acid is probably at its lowest ebb. This circumstance, together with the usual restricted diet, particularly if convalescence is delayed by complications, causes lime starvation and encourages successful infection with tubercle bacilli.

Acute dry pleurisies occurring in the course of pulmonary tuberculosis are plastic effusions, and are evidence of an attempt at healing. It is a mistake to regard them as extensions of disease. Plastic effusion is the normal means of cure in tuberculosis, and is similar in purpose to the callus thrown about the fragments of fractured bones in the process of their repair. Plastic effusion must always precede spontaneous recoveries. Spontaneous recoveries occur when the subjects of disease regain the power of assimilating lime. It can readily be understood how this may take place quite accidentally so far as conscious effort is concerned. A tuberculous individual might take foods containing lime without benefit for a long period, and then, because of change of season, or change of climate, caprice, or from any imaginable cause, acid, in the form of fruit, beverage, condiment, or fermented dish, was added to the diet, thereupon the assimilation of lime would be resumed and improvement follow. The administration of hydrochloric acid, casein, and lime phosphate is an orderly plan to restore the missing essentials by means of which the suspended natural forces in every patient are again put in motion and plastic effusion assured. If the lesion is extensive enough plastic effusion produces symptoms sufficiently marked to be recognized as acute dry pleurisy. If the lesion is small the symptoms may be so slight as to pass unrecognized. Serous effusion is evidence of lack of lime because the effusion is not plastic.

The symptoms of plastic effusion are the symptoms of acute pleurisy, and vary in intensity in different patients. They begin with pain, temperature, and physical signs of pleurisy. Pain may be slight or severe, temperature may be only slightly elevated, or in some cases reach 102° and higher. The acute symptoms may last a week, more or less. Physical signs vary in intensity. As a rule the more marked the lung lesion the more marked the physical signs of pleurisy. After the acute symptoms subside and the effusion begins to organize, creaks and dry rubs are marked. Moist râles gradually disappear.

As the original lesion heals the most marked signs of effusion may either disappear altogether or persist for some time after. The more extensive the original lesion, the longer the signs of organized effusion remain. This is true particularly over and about cavities. Serous effusion has so far never been noted. The time at which these symptoms first make their appearance varies. I have known the effusion to appear witin three weeks after beginning treatment, and in other instances to be delayed for more than five months. Broadly speaking, the time of its occurrence may be put for the majority at between the sixth and sixteenth week after beginning treatment. During the past two years there has been a small number of patients who reached apparent cure without physical signs of plastic effusion. The extent of disease was small and the effusion produced no signs.* Plastic effusion occasionally occurs in situations where no lesion had previously been noted. It may occur more than once in the same patient.

Eighteen cases have been observed in which plastic effusion was accompanied by extensive consolidation, involving a part, and in two instances a whole lobe, unaccompanied by rise of temperature, quickened pulse, or other rational symptoms of pneumonia. These consolidations in seven cases persisted for months, and finally cleared after being treated by a lessened amount of milk and eggs and the omission of dilute hydrochloric acid. This modification arose from the idea that the consolidations might be due to excessive amounts of plastic effusion having been poured into the air vesicles. The correctness of this conception can be confirmed only by autopsy, and I have no observations of such examinations to report.

To insure the absorption of lime in an assimilable form it is necessary to supply lime phosphate, casein, and dilute hydrochloric acid together. No one alone will answer. They should all be present in the stomach at the same time. The administration of milk and eggs to which dilute hydrochloric acid has been added, to be described later, fulfils this requirement.

Treatment based on the theory outlined in the foregoing was begun in September, 1906, at the Thompson street rooms, and has continued ever since. Two reports have been published. A final report cannot be made until the few remaining patients of the group selected for observation have either recovered, died, or stopped treatment for any cause. Comparisons can, however, be made between the results so far obtained from this treatment, and results obtained from treatment based on other theories. No comparison can be made between results obtained at the Thompson street

*These patients were not among the group selected in 1906 for observation of results of treatment.

rooms and those obtained at other dispensaries, because, so far as I am aware, there are no other reports of the results of systematic curative dispensary treatment in existence. The only reports available for comparison, therefore, are those from sanatoria. Such comparison on the whole is fair because by far the greater number treated at sanatoria are ambulatory cases. Ambulatory cases only can be properly treated at a dispensary.

Treatment at sanatoria is based on the theory that rest, pure air, an outdoor life, and good, wholesome food are cardinal factors in the cure and prevention of tuberculosis. To obtain this treatment all patients must give up their work and live in an institution which is situated in the country. Carried to a logical conclusion, the practice of this theory means, if it means anything, that all consumptives and those predisposed to the disease should live in such institutions at least until cured, for all the essentials for cure can be obtained nowhere else. Those who are uncured should certainly stay, and those who are apparently cured should remain in order to prevent a recurrence. It requires years of treatment to bring about a cure. As a matter of fact, the great majority of patients remain at sanatoria but a few months, after which, whether apparently cured or not, they return to their original surroundings—surroundings which, according to the theory, present insurmountable obstacles to both cure and prevention. Does not this practice stultify the theory? What hope does this belief afford an incompletely cured wage-earner after his return home from a sanatorium where he can neither rest, breathe pure air, nor lead an outdoor life? If it is urged that any stay in a sanatorium, even if short, is of benefit in delaying the inevitable end, then it would naturally be supposed that this benefit would be extended first to those whose need was most urgent and that, in the selection of patients for admission to sanatoria, the advanced rather than the early stage cases would be given preference. Such is not the practice. Early stage cases are always selected when possible.

Treatment at the Thompson street rooms is based on the theory that a specific diet and fresh air are the chief factors in the cure and prevention of tuberculosis. Wage-earners with uncomplicated pulmonary tuberculosis in any stage of the disease are admitted for treatment so long as they are properly ambulatory cases. All patients live at home, their labor is uninterrupted, and they can remain under treatment or observation for the remainder of their lives if necessary.

The percentage of apparent cures reported from six well-known sanatoria, the result of treatment of patients in all stages of the disease, averages 20 per cent. The percentage of apparent cures obtained at the Thompson street rooms to date, the result of treatment of patients in all stages of the disease, is 61.7 per cent.

The Thompson street rooms are kept perfectly clean. Floors, benches, chairs, and tables are gone over daily; walls and ceilings once a week. Damp cloths only are used, and are burned at the end of each day. Two women are employed for cleaning, and do their work between the morning and evening dispensary hours. Rules for the care and disposal of sputum are printed and a copy given each patient at the first interview. These rules are carefully explained, and their importance emphasized. Paper napkins are furnished for expectoration and to hold before the face when coughing or sneezing. Drinking vessels are sterilized after each dispensary hour. The number of patients is limited to fifty, and every patient is required to report twice daily in all weather, Sundays and holidays included; in the morning after breakfast, on the way to work, and again after the last meal in the evening. The hours are 7 to 8.30, morning and evening. Once a week all patients are weighed and the men and women examined and notes made of their condition on alternate Sunday mornings. Sunday is selected for weighing and examination, because it is not a work day, and no time is lost from labor. Individual supervision is one of the highly important details, hence the advantage of having patients report twice daily and limiting the number to fifty. During these visits patients drink the milk-egg-acid mixture to be described later, and the emulsion of mixed fats, and are instructed.

The importance of the coming of patients to the dispensary twice each day and their drinking the prescribed foods in the presence of the nurses is patent. Under these conditions there can be no deception or wastefulness on the part of the patient, or uncertainty on the part of the physician that each patient obtains these indispensables, that they are properly prepared, and that they are imbibed at the proper time. These visits lead to complete knowledge of the life and habits of the patients, thus discovering faults which call for correction, and besides, occupying, as they do, practically all of their leisure time, evil associations, if such exist, are destroyed. Having one member of the family in such long and intimate association has a very direct bearing upon the prevention of tuberculosis in that it enables the dispensary to reach the whole family, particularly the children, who are the oncoming recruits of the disease, and to direct their regimen.

The nurses, three in number, are present at all dispensary hours to distribute food, interview patients, and carry out the practical instruction. They are former patients. The physician is present three evenings a week to examine new patients, receive reports of nurses, issue instructions, and correct errors. This requires about one hour for each visit. Sunday morning, when patients are weighed and examined, occupies about one and one-half hour additional of the physician's time. One of the nurses visits the home of each patient at least once, after which it is usually necessary only to send for some member of the family to come to the rooms in order to correct errors that may be discovered. The physician never visits the homes of patients. For the care of intercurrent troubles patients are instructed to call their family physician.

As stated before, ambulatory cases only are accepted for treatment. The majority are working people, and they continue to work while under treatment. The dispensary hours are arranged with this end especially in view.

No patient is admitted whose sputum does not show tubercle bacilli.

Patients are considered apparently cured when physical signs of disease are no longer heard and tubercle bacilli have disappeared from the sputum. Six examinations, two weeks apart, are required.

The treatment of dispensary patients may be considered under three heads, viz.: First, education and management; second, general details, and third, diet and care of digestion.

Education and Management.—All patients should clearly understand that their disease is consumption, and that in the great majority of cases ap-

parent cure and cure are accomplished only after years of treatment. Unless taught otherwise, it seems to be a natural tendency for the average patient to assume that he or she is cured after gaining weight and strength, even though the cough and expectoration containing tubercle bacilli remain undiminished. They have little idea of the length of time required to bring about apparent cure, and education in this regard prevents disappointment and strengthens control. They are taught that after gaining proper weight and strength continuance of treatment in no way interferes with rational enjoyment and the reasonable pursuits of life. It is made clear that the hope of cure rests upon their faithfulness in carrying out the prescribed rules of correct living. They are held to a strict accountability, and if found weak and persistently obstinate, dismissed. This sometimes becomes necessary. It is folly to allow looseness in discipline. Beyond a reasonable point toleration works serious injustice to the faithful and produces discontent. The great majority of patients are reliable.

General Details.—Clothing: The commonest fault in the matter of dress among the tuberculous, during cold weather, more especially, is overclothing. Heavy underwear, all neck wraps, chest protectors, and corsets are forbidden. The patients are directed to wear heavy soled shoes, and in wet weather overshoes, and always to keep the feet dry and warm. Most houses are overheated, and patients are taught that the best safeguard against colds in winter is to wear light underclothing, in order to avoid sweating while at rest, and, on leaving the house, a heavy outer garment which can be removed on again reaching shelter. Instead of neck wraps they are taught to bathe the neck and chest in cold water on rising in the morning.

Exercise: Exercise undertaken solely for the purpose of influencing health is forbidden. As stated before, these patients work, and are encouraged to continue their occupations except in instances when it is known that the work is injurious. In such cases a change is advised. Occupation is considered desirable, even though it involves a good deal of exercise. The use of dumb-bells, chest-weights, Indian clubs, and breathing exercises is forbidden.

Fresh Air: Fresh air, being a form of food, all patients are instructed to obtain as much of it as possible. Because they work and cannot in the great majority of cases control the supply of fresh air during the day, stress is laid upon the necessity of having the bedroom windows open wide in all weather. They are told that they are expected to keep comfortably warm in bed, but must be sure to breathe the cold, fresh air; they are also advised to occupy a sunny room and preferably alone.

An interval of at least five hours between meals is insisted upon. Breakfast at 7 or 7:30, mid-day meal at 12 or 12:30, and the evening meal at 6 or 6:30 o'clock. No food is eaten between meals, excepting the extra milk allowed new patients prior to the appearance of plastic effusion. They are directed to avoid crowded places of amusement, and remain eight hours in bed at night. All medicines excepting those prescribed are forbidden.

Special Symptoms.—Cough, pain, night sweats, and hoarseness receive no special treatment. Patients are taught to ignore and, when possible, suppress cough. No medicines are given for the relief of this symptom. Diarrhea and looseness of the bowels are treated with castor oil and other cathartics, if necessary. Nausea and vomiting are caused by incomplete emptying of the bowel, and are relieved by cathartics. Blood-stained sputum and small hemorrhages are ignored. When severe hemoptysis occurs the patient is advised to keep quiet for a few days. In such case some member of the family comes to the dispensary daily for the milk-egg-acid mixture, which the patient continues while absent. No special treatment is employed for this symptom.

Weight.—Gain in weight is insisted upon in all cases until in the judgment of the physician the total amount gained is sufficient. This weight is then maintained. The greater number of patients are much under normal upon beginning treatment, but occasionally a patient appears in whom the required gain is small. Increase in weight is an indication of improved nutrition. The fact that individuals and various members of their family have always been under normal weight is not a good reason for failure to gain. Most patients who have been under treatment for a long time are forbidden to increase their weight because the maximum amount has been achieved. Long experience has taught that those who fail to gain, unless undergoing an exacerbation, are either disobedient or too poor to provide proper food. Regular weighing (once a week, at least) is absolutely necessary if the treatment is to be carried on intelligently. The patient should always weigh at the same hour, dressed in the same clothing, or, better still, without clothing, and use the same scale. At my rooms women are weighed in their night dresses and men in trunk-hose.

Food and Care of Digestion.—In arranging the diet for dispensary patients very explicit directions are given concerning the kind and quantity of a few articles of food and only the most general regarding others. The reason for this is obvious when it is remembered that these patients live at home, and necessarily purchase and prepare their own food. It is all important that they receive a sufficient quantity of phosphate of lime, casein, and other protein, and fat. The necessary daily amounts of foods containing these constituents in quantity are customarily replaced by other articles of food which may be more palatable, but are less important. Vegetables, with the exception of wheat and the pulses, are usually thought of as sources of carbohydrates and salts, and the daily amount consumed is left to the discretion of the patient so long as progress is satisfactory.

The main sources of phosphate of lime are milk and eggs; of protein, milk, eggs, bread, and meat; of fat, milk, eggs, and emulsion. Excepting wheat and corn meal (as bread) no directions are given for eating cereals. If patients are fond of bread, butter, and milk, they invariably do well, but if they do not eat bread and butter from choice, as commonly happens, they are directed to eat one or more generous slices of bread liberally spread with butter, with each meal. The pulses, peas, and beans are recommended in the form of soups, but are practically ignored as sources of protein, though very rich in this constituent. Ordinarily no special instructions are given in regard to the consumption of meat.

Practically then specific directions for the consumption of a daily amount are confined to the following foods: Milk, eggs, bread, butter, and fat emulsion. With the exception of milk and fat emulsion, the amounts of which remain fixed after

a certain period, the daily quantities of these foods are determined by the gain or loss of weight of each individual. It will be understood, therefore, how necessary it is that patients should be weighed regularly.

These are, of course, merely general principles. No one rule of feeding will apply to all patients, or to the same patient under all circumstances. The individual must be studied. The need for large quantities of food is passed. Since the use of dilute hydrochloric acid the compulsory daily amounts are not burdensome, and no one has difficulty in meeting requirements.

Alcohol in all forms, tea, coffee, chocolate, cocoa, and thin soups are forbidden.

No change in diet is made the first week of treatment except that all receive fat emulsion and abstain from forbidden articles of food. Cough mixtures and all other medicines are stopped. Cathartics are freely administered, and an effort is made to clean the intestinal tract thoroughly. Patients are not expected to gain the first week, and frequently lose weight. Beginning with the second week, the milk-egg-acid mixture is begun. Both men and women drink a quart of this mixture at the dispensary daily, a pint at the morning hour, and a pint at the evening hour. In addition the men carry home and drink during the day a quart of milk to which has been added four drachms of dilute hydrochloric acid, and the women one pint of milk to which has been added two drachms of hydrochloric acid. This extra milk is employed until the patient develops plastic effusion, when it is stopped. The milk-egg-acid mixture, one quart, which is taken at the dispensary, is continued until the end of treatment.

Preparation of the Milk-Egg-Acid Mixture.—At the dispensary two eggs are beaten, strained, and mixed with sufficient milk to make one quart. To each quart of this mixture four drachms of dilute hydrochloric acid (U. S. P.) are added and stirred until thoroughly mixed. The mixture is then bottled and put in the ice chest. The appearance of the curd varies. The warmer the milk and egg mixture when hydrochloric acid is added, the thicker the curds. The curds are, therefore, sometimes thicker and more noticeable than at others, but are always soft, rather fine, and in no way disagreeable to drink. The taste of raw egg is much improved by the acid. When hydrochloric acid is added to milk it is, of course, largely combined by the various constituents contained therein, and as some free acid is necessary in order to activate rennet zymogen, the proper amount to be added is of moment. The amount given above was adopted after long experimentation, and has not been changed since June, 1909.

Eggs.—Two of the whole number of eggs are taken in the milk-egg-acid mixture at the dispensary. The remainder are swallowed immediately after meals. If a patient fails to gain weight when the daily number of eggs is six, care should be taken to see that a sufficient quantity of bread, butter, and vegetables, particularly the former, is eaten before increasing the number of eggs. This is a matter of consequence. Eggs are uncooked and patients are allowed to swallow them with or without milk (yolk unbroken), as preferred.

Fat.—An ample supply of fat in the diet of the lime-starved is essential. The beneficial results following the administration of fat in rickets, scrofula, and tuberculosis are mentioned by all observers. There is some important physiological relation, as yet unexplained, between fat and lime. In this connection it is interesting to note that studies in pathological calcification show that the presence of fat is necessary for the deposition of lime. Caseation of the tubercle, therefore, affords suitable soil for deposition of lime salts and the formation of lime soaps, and leads to healing by calcification. Fibroid limitation of the tubercle is, of course, the result of plastic effusion. To supplement the fat contained in milk and eggs I employ an emulsion of mixed fats. Beginning with one-half ounce, dissolved in a whole glass of hot water, night and morning, and adding one-half ounce every three days until two ounces are taken with each dose, in the same amount of water. This is the maximum dose, and is continued throughout treatment.

Cathartics.—With very few exceptions all these patients are constipated, or have insufficient daily evacuations. This causes lack of appetite, nausea, often vomiting and so-called bilious attacks, and occasionally an increase of temperature. Diarrhea is not uncommon as a result of constipation and many suffer from hemorrhoids. The relief of these disorders alone is reason for the systematic administration of cathartics, but when it is remembered that these patients are suffering from a wasting disease and, in order to combat it, must of necessity consume more food than is actually needed for their daily physiological requirements, it is evident that some provision must be made for getting rid of the extra amount of waste material resulting from the extra amount of food consumed. It is a rare exception when a patient is able to keep the large bowel empty without the aid of laxatives. The systematic use of cathartics increases digestive capacity, hastens absorption, aids the removal of circulating poisons, and reduces fever. All patients are taught that daily movements are essential, and each patient is especially studied in order to learn the amount and kind of medicine necessary to accomplish the desired result. With the exception of castor oil, no point is made of any particular medicine. Castor oil, two tablespoonfuls, is always administered to new patients the first night and as a rule all patients take it at least once a week. A cathartic of some kind is taken every day. In addition to castor oil I employ compound rhubarb pill, cascara, licorice powder, salines occasionally, and, when the use of calomel is desired, compound cathartic pill.

Treatment of Children.—Seven children of patients undergoing treatment at the dispensary have been treated. Oldest, seventeen years; youngest, five years. These children were anemic, most of them under normal weight, and all showed signs of previous attacks of rickets. Physical inactivity was most noticeable, and one child in particular was dull mentally. The special treatment consisted in adding daily one quart of the milk-egg-acid mixture and the emulsion of mixed fats, in doses not exceeding one ounce, to the diet. Two drams only of dilute hydrochloric acid were added to the quart of milk-egg-acid mixture prepared for the youngest child; the remainder were given the usual mixture containing four drams of acid. All the children were greatly benefited. The improvement consisted in color, increase in weight (small in the majority), height, and vigor. The latter most marked.

These children were selected for treatment because the parents were trustworthy and intelligent,

and the treatment could be managed from the dispensary. I at one time attempted to treat all the children of all the patients, but had to abandon the attempt because I found that, in most cases, without special nurses to visit the homes, instruct the household, and establish a routine, no exact work was possible. This involved more outlay of money and time than I felt could properly be added to my present work. Enough experience was gained, however, to convince me that with efficient aid this feature can be made a most important part of dispensary work.

*Treatment of Pregnancy and Lactation.*—Large quantities of lime are furnished by the mother for the development and growth of the fetus and later, during lactation, for the further growth and development of the infant. The importance for both mother and child of preventing lime-starvation during pregnancy and lactation is obvious. Tuberculosis following pregnancy and lactation is often observed. Rickets is the commonest disease of childhood.

Six cases were treated. Two of the women were cured dispensary patients, each of whom was treated through two pregnancies. The special treatment consisted in the daily administration of one quart of the milk-egg-acid mixture and the emulsion of mixed fats. Cathartics were employed as described above. The benefits observed were no decayed teeth, more comfort and well-being during pregnancy. Lactation was normal with less than the usual loss of strength. The chief result noted, however, was the very unusual vigor and activity of the children and their general good health.

*Treatment of Private Patients.*—The treatment of private tuberculous ambulatory patients is conducted in the same manner, with few modifications, as the treatment of dispensary patients described in the foregoing pages. If the physician and patient together undertake this or any other treatment as an experiment the probabilities are that the experiment will end in failure. The physician alone should direct the treatment and he should dominate the patient. Some member of the family had better be instructed by the physician to assume responsibility in the preparation and administration of the milk-egg-acid mixture, emulsion, and cathartics, and in establishing a routine. After this has been accomplished the physician need see his patient but once a week, when he or she is weighed, examined, and instructed. If it is found convenient to do so it will be more agreeable for these patients to make the milk-egg mixture in the morning without the dilute hydrochloric acid and, when about to drink, to each eight ounces of this mixture add sixty minims of acid and stir thoroughly.

239 Thompson Street.

## FURTHER EXPERIENCE WITH THE HIGH CALORY DIET IN TYPHOID FEVER.

By MONTGOMERY HUNT SICARD, M.D.,

NEW YORK.

INSTRUCTOR IN MEDICINE AND THERAPEUTICS, CORNELL UNIVERSITY, NEW YORK; VISITING PHYSICIAN NURSERY AND CHILDS HOSPITAL; ADJUNCT ASSISTANT VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

It is not my aim to write an exhaustive treaty on this subject, which is occupying so much space in medical literature, but merely to present a few interesting features of this method of treatment, contrasting them with the various methods of feeding which have been, and still are in vogue.

First, it may be said, that until a few years ago the percentage mortality of typhoid fever had remained practically the same for many years; the percentage of complications had remained the same for an equal period. The prevailing picture of typhoid patients was one of dry leathery tongue, characteristic apathy, low muttering delirium, subsultus tendinum, emaciation, sometimes furunculosis, asthenia and incontinence; this picture was characteristic, was not infrequent, and gave promise of dissolution which was averted, seemingly, by the hand of Providence alone. My contention is that this state of affairs has changed since the greater feeding of patients has been in vogue.

It is interesting to note the various changes promulgated in the diet from time to time, seemingly regardless of the loss of nutrition entailed, hence the lessened resistance so caused. Poor nutrition means lowered resistance, inability of phagocytes to contend with the invasion of bacteria, inability of the constructive to cope with the destructive processes of metabolism. The whole situation was sacrificed to the fear of intestinal ulceration, anticipated hemorrhage and perforation, and the danger was enhanced to the greatest extent by a continued refusal on the part of the profession to build up reduced material by increasing the dietary. As a result, the loss of weight was great, convalescence prolonged, and inanition temperature sometimes present; the hunger of the patients was pathetic; in hospital practice they would beg food from their friends, or steal it from their neighbors.

In past years there have been (and there still are) those who have advocated entire elimination of milk from the dietary, "because it forms a good culture medium for typhoid bacilli, because of its difficulty of digestion and its proneness to cause digestive disturbance."[1] This total cutting out of milk from the dietary has not been thought necessary by the majority of practitioners, because its rôle as a culture medium is of little importance when we remember that typhoid fever is a bacillemia; also milk is indigestible to only a few individuals, and if found to be so it can be peptonized or even stopped. Other writers advocating a gruel or a broth diet have said that emaciation occurs independently of taking food, suggesting that but little food is assimilated, and that what the patient loses in food is more than compensated for by diminished toxemia: they claim that fasting reduces the temperature, brings rest to the intestines with lessened danger of hemorrhage and perforation, and enhances the effect of hydrotherapy; also that recrudescences are due to dietetic errors.

In refutation of the non-assimilation and non-absorption of food in typhoid fever, Du Bois' experiments[2] have proved conclusive. He has shown that with an intake of 65 to 118 grams of proteid, the loss was usually under 10 per cent.; the normal loss on the same diet being 7.9 per cent. The fat loss in the second week when the temperature was high, with an intake of 147 to 200 grams, averaged 8.8 per cent.; in the third and fourth weeks, with an intake of 150 to 200 grams, the loss was 4.15 per cent.: the normal loss with an intake of 164 grams, was 2 per cent. (Rubner found that a normal man taking 79 grams daily, in milk, lost 7.1 per cent. in the stools, and a man taking 214 grams a day, in butter, lost 2.7 per cent.) The carbohydrate loss in patients taking from 215 to 567 grams was only 0.1 to 0.3 per cent.; the control, on 249 grams, lost 0.1 per cent.

A trial with liberal feeding will soon convince anyone that emaciation is not independent of taking food, but on the contrary, weight is very dependent upon the amount of food taken; of course, a certain loss of weight will occur anyway, due to the toxemia, or the toxogenous destruction of proteid, but weight is certainly better sustained by a liberal diet; that the taking of food increases the toxemia is not true, and that starvation decreases the temperature is not true: experiments[3] have shown that during starvation, heat production remains constant until near the end, when a great output of nitrogen occurs. While recrudescences may at times be due to dietetic errors, they are reinfections, and occur independently of taking food. Von Hoeslein has shown that during typhoid fever, digestion is not more than 10 to 15 per cent. below normal.

There is less diarrhea with high ealory diet, than with fluids alone, and the stools present a more normal appearance than do the stools of other methods of feeding, and contain practically a normal quantity of nitrogen, which is not true of the stools of starvation. It must be conceded that cases with gastroenteritis are apt to do badly; the gastritis is a sign of toxicity; they are hard to feed and if milk disagrees, recourse must be had to some substitute.

Six hundred cases fed on a liberal diet have been analyzed by Kinnicutt,[4] who concludes that relapses were not increased and that hemorrhage and perforation were diminished.

Coleman, in his 111 cases fed on high calory diet, finds that relapses are not affected, while hemorrhage and perforation are lessened.

Shaffer[5] found that a patient with typhoid fever rarely received more than 50 per cent. of his dynamic needs, and that this contained proteids far in excess of the normal proportion.

With a purely milk diet 4,000 grams, or four quarts, would be necessary to satisfy a daily requirement of 2,800 calories; this is far too great a quantity to take, and besides, furnishes 140 grams of proteid, or about twice as much as is necessary; our aim must be to reduce the bulk of milk to a normal quantity such as one and a half to two quarts, and increase its fuel value by the addition of fat and carbohydrates. Knowing, as we do, by the experiments of Von Noorden, Rubner, Voit, and others, that during fever the metabolism of the body is increased, that the fat reserve of the body is called upon, after which a loss of proteid occurs, it becomes incumbent upon us to protect the body from this threatened destruction. This can be done by increasing the carbohydrate and fat intake, in order that the proper fuel value of 2,800 calories be given. Folin[6] showed that in starvation, nitrogen metabolism can be reduced one-third by the use of carbohydrates. Chittenden thinks that 60 grams are enough to maintain nitrogen equilibrium; the German authorities, however, place it higher, 80 to 100 grams.

Carbohydrates then, being the best sparers of proteids, it is with this ingredient chiefly that we attempt the caloric increase; we must also attempt to give the usual amount of protein[7] of 60 to 100 grams a day, for this is as important as the total fuel value. Fat fed alone retards the loss of body proteid comparatively little, but spares an equivalent amount of fat.

*Carbohydrates* are best supplied in the form of milk sugar, cereals, bread, toast, crackers, baked or mashed potatoes, and proprietary foods; they are the best proteid sparers available, and milk sugar is preferred because of its lesser bulk and high caloric value. Milk sugar is best dissolved in hot water ounce for ounce, brought to the boiling point and immediately removed, otherwise the sugar will crystallize; it is best administered by adding 10 grams, or 2½ drams of this sugar solution to each feeding, increasing to 20 grams or 5 drams in the course of a few days; it is usually well borne, but some people object to its sweetness and it may have to be increased more slowly than the above; patients who object to its sweet taste in milk will often take the same amount in custard, lemonade, or ice cream. Its ill effects are shown chiefly in distention, also to a lesser extent in nausea and vomiting, and it should be cut down or stopped for the time being; when resumed it should be done with care. Two hundred and fifty grams, or 8 ounces by weight, equals 100 calories.

*Fats* are best given as cream, butter, and cocoa; a good beginning is by adding one ounce of cream to each milk feeding, after a few days increasing it to 2 ounces; 200 grams in the twenty-four hours is a good quantity, and equals one ounce to each three-hourly feeding. Five hundred grams or one pint equals 1,000 calories. Fat tolerance varies considerably in different individuals; most people can take fats if fed gradually and with care, but there are those in whom fat causes distress, eructations, nausea and vomiting, and diarrhea; in this case they must be reduced, and then tried again cautiously. Acidosis resulting from high fat feeding has not been observed.

*Proteins.*—The attempt should be made to give food of as high protein content as is possible under the circumstances; this means from 60 to 100 grams of protein a day; while more than this is often taken in health, the excess is not necessary, and becomes burdensome. Although fats and carbohydrates are protectors of proteid during the increased tissue waste brought about by the pyrexia, bacteriemia, and under-feeding, the surest way of making good the protein loss is by protein intake; Voit's experiments in starvation showed that some of the animals used had a considerable amount of fat even after death, proving that the fat was not entirely used as a sparer of proteid. In health, nitrogen equilibrium is maintained by an intake of 100 grams of protein per diem, and is represented by a urinary output of 16 grams of nitrogen per diem, and a fecal output of about 1.1 grams per diem (Hammarsten).

| | Protein Intake | Nitrogen Intake | Nitrogen Output | |
|---|---|---|---|---|
| Fat[8] | 100 grams | ..... | Urine | 14.4 grams |
| Sugar | 250 grams | ..... | Feces | 1.1 grams |
| Protein. | 100 grams | 15.5 grams | | 15.5 grams |

Coleman[9] contends that though these figures (100 grams) are enough to maintain nitrogen equilibrium in disease, there may be an increased demand for proteid intake during convalescence to repair the damage already inflicted.

The most available food for maintaining proteid equilibrium are milk, eggs, and the protein containing carbohydrates. One and a half quarts of milk equals 53 grams of protein; two eggs equal 14 grams of protein; 90 grams, or 3 ounces, of cereal equal 3½ grams of protein; 33 grams of bread (one slice) equal 1.5 grams protein. Here, then, are 72 grams of protein which can be utilized for an arbitrary working basis, and can be diminished or increased, as the case demands. Beef broths and beef juice are of such low protein content and low

caloric value, that they are not of much consequence from this point of view, but may be used for variety, and to stimulate appetite. Meat itself may disorder digestion and prove irritating to the kidneys owing to its purine content.

From a series of experiments by Coleman and Du Bois on total metabolism by means of the Benedict respiratory apparatus, I quote briefly from Coleman's article, "The greatest amount of heat produced by any patient was 48 calories per kilo a day, the majority giving off about 35 calories per kilo a day. On this basis the high calory diet gives 1,000 or 2,000 more calories than are expended in twenty-four hours, and if the patients do not receive this they lose both nitrogen and weight; later in the disease the excess is used in storing fat."

*Milk* forms the basis of high caloric feeding; for while it may be supplemented later in the disease, it forms the fundamental element of the dietary in the beginning; it is usually well taken and liked; but its continued use becomes irksome, and there are some persons who can not take it at all, though among many of these the distaste is purely imaginary. The average quantity which can be handled by patients is from 1½ to 2 quarts a day; but there is a definite limit to the power of digesting it, and that limit is shown by abdominal distention and curds in the stools; if undigested it should be cut down in quantity or peptonized, or stopped, as indicated. If necessary it may be supplanted by malted milk, malt soup, other proprietary foods, and broths; this, however, is unfortunate, for without milk and its derivatives such as zoolak, koumyss, etc., and the foods made from milk, as junket, custard, cocoa, etc., it is difficult to provide variety in feeding, difficult to provide an appetite, difficult to give high fuel values, consequently more difficult to maintain weight.

One liter of milk consists of 40 grams of fat, 45 grams of carbohydrate, and 35 grams of protein; its fuel value is 700 calories as shown by Rubner's table.

| | | |
|---|---|---|
| Fat | 4 %x1000 gm. 40 gm.x9.3 (cal. value 1 gm.) | 732 calories |
| Sugar | 4.5%x1000 gm. 45 gm.x4.1 (cal. value 1 gm.) | 184.5 calories |
| Protein | 3.5%x1000 gm. 35 gm.x4.1 (cal. value 1 gm.) | 143.5 calories |
| Total value one liter of milk | | 700 calories |

The following table gives the necessary values for making up a standard milk dietary:

| | Grams | Ounces | Calories | Grams Protein |
|---|---|---|---|---|
| Milk | 1000 | 32 | 700 | 35 |
| | 250 | 8 | 170 | 8 |
| | 30 | 1 | 20 | 1 |
| Cream | 500 | 16 | 1000 | 18 |
| | 30 | 1 | 60 | 1 |
| Milk sugar | 250 | 8 | 1000 | ..... |
| | 30 | 1 | 125 | ..... |
| | 18 | 1 (vol.) | 75 | ..... |
| Cane sugar | 50 | One flat tablespoon | 100 | ..... |
| | | One lump | 16 | ..... |

Patients in hospital practice are usually seen about the fourth or fifth day, having often been neglected, and having lost considerable weight, perhaps 10 or 15 pounds.

The first day a milk diet is ordered, 6 ounces every three hours, which is about 1½ quarts in the twenty-four hours, having a caloric value of 1,000.

The second day a diet is given of approximately 1,500 calories, consisting of:

| | | | |
|---|---|---|---|
| Milk | 1500 c.c. | 1½ qts. | 1050 calories |
| Cream | 120 c.c. | 4 ounces | 240 calories |
| Milk sugar | 40 gm. | 1½ oz. sugar sol.* | 200 calories |
| | | | 1490 calories |

*The sugar solution is one ounce of milk sugar dissolved in one ounce of water.

This makes eight feedings, each of:

| | | |
|---|---|---|
| Milk | 180 c.c. | 6 ounces |
| Cream | 15 c.c. | ½ ounce |
| Milk sugar | 5 gm. | 1½ drams sugar sol. |

The third day about 2,000 calories, consisting of:

| | | | |
|---|---|---|---|
| Milk | 2000 c.c. | 2 quarts | 1400 calories |
| Cream | 120 c.c. | 4 ounces | 240 calories |
| Milk sugar | 80 gm. | 2½ oz. sugar sol. | 312 calories |
| | | | 1952 calories |

This makes eight feedings, each of:

| | | |
|---|---|---|
| Milk | 210 c.c. | 7 ounces |
| Cream | 15 c.c. | ½ ounce |
| Milk sugar | 10 gm. | 2½ drams sugar sol. |

On the fifth day approximately 2,200 calories:

| | | | |
|---|---|---|---|
| Milk | 2000 c.c. | 2 quarts | 1400 calories |
| Cream | 250 c.c. | 8 ounces | 500 calories |
| Milk sugar | 80 gm. | 2½ oz. sugar sol. | 312 calories |
| | | | 2212 calories |

This makes eight feedings, each of:

| | | |
|---|---|---|
| Milk | 210 c.c. | 7 ounces |
| Cream | 30 c.c. | 1 ounce |
| Milk sugar | 10 gm. | 2½ drams sugar sol. |

At this point the milk dietary is supplemented by other feedings, and articles are added one by one, the attempt being made to find things agreeable to the patient's taste. The dietary will be resumed following the ensuing table, which gives the caloric values, and protein content of the extra foods which can be used:

| | Ounces | Grams | Calories | Grams Protein |
|---|---|---|---|---|
| Egg (one) | 2 | 60 | 80 | 7 |
| Bread (ordinary slice) | .... | 33 | 80 | 2 |
| Toast | .... | 33 | 80 | 2 |
| Crackers | 1 | 30 | 118 | .... |
| Butter (one pat) | ½ | 15 | 100 | .... |
| Cereal cooked (one serving) | 3 | 90 | 100 | 3.5 |
| Potato (one medium) | .... | .... | 85 | .... |
| Junket (one serving) | 6 | 180 | 200 | 3.5 |
| 1 ounce milk sugar<br>5 ounces milk<br>½ junket tablet<br>1 ounce cold water<br>Vanilla to flavor | | | | |
| Cocoa with milk | 6 | 180 | 315 | 4 |
| 1 rounding teaspoon cocoa<br>1 ounce milk sugar<br>4 ounces milk<br>1 ounce cream | | | | |
| Coffee | .... | .... | 300 | 2 |
| 2 ounces cream<br>1½ ounces sugar | | | | |
| Ice cream | 5 | .... | 520 | 7 |
| Cane sugar (one flat tablespoon) | .... | .... | 100 | .... |
| Baked custard | .... | 50 | 360 | 7 |
| 1½ ounces milk sugar<br>6 ounces milk<br>One egg<br>Vanilla | | | | |
| Soft custard | .... | .... | 500 | 7 |
| 8 ounces milk<br>1 egg<br>2 ounces milk sugar<br>Vanilla, salt, caramel | | | | |
| Bread pudding | .... | .... | 560 | 7 |
| 1½ ounces of milk sugar<br>6 ounces milk<br>1 egg<br>1 slice bread<br>½ ounce butter | | | | |
| Lemonade | .... | .... | 480 | .... |
| 4 ounces milk sugar | | | | |
| Applesauce | 3 | 90 | 90 | .... |
| Rice boiled | 3 | 90 | 360 | 3.5 |
| Malt soup (Loefflund's) | 32 | 1000 | 720 | .... |
| Malted milk (in 1 quart water) | 4 | 1000 | 495 | .... |
| Broth | 8 | 250 | 64 | .... |
| Beef juice | 3 | 90 | 25 | .... |
| Buttermilk | 32 | 1000 | 350 | 32 |
| Whey | 32 | 1000 | 450 | 20 |
| Zoolak | 32 | 1000 | 620 | 39 |
| Koumyss | 32 | 1000 | 400 | 20 |
| Whiskey | 1 | 30 | 85 | .... |
| Alcohol | 1 | 30 | 210 | .... |

Alcohol is isodynamic with 23 grams of fat, and with 52 grams of carbohydrate.

Fruit may be given except when diarrhea exists.

To revert then to the standard dietary; on the sixth day about 3,000 calories are given:

| | | | |
|---|---|---|---|
| Milk..... | 1500 c.c. | 1½ qts. | 1000 calories |
| Cream..... | 125 c.c. | 4 ounces | 250 calories |
| Milk sugar.... | 125 c.c. | 4 ounces | 500 calories |

In seven feedings, at 9 A.M., 1, 3, 7, 9, 12 P.M., and 4 A.M., each feeding consisting of:

| | | | |
|---|---|---|---|
| Milk..... | 180 c.c. | 6 ounces | |
| Cream..... | 15 c.c. | ½ oz. | |
| Milk sugar.... | 15 c.c. | ½ oz. | |

At 7 A.M.:

| | | | |
|---|---|---|---|
| Toast (one slice) | | | 80 calories |
| Butter..... | 15 gm. | ½ oz. | 100 calories |
| Egg (one)..... | | | 80 calories |

At 11 A.M.:

| | | | |
|---|---|---|---|
| Egg (one)..... | | | 80 calories |
| Bread (without crust) | | | 100 calories |
| Butter..... | 15 gm. | ½ oz. | 100 calories |
| Junket..... | 180 gm. | 6 ounces | 200 calories |

At 5 P.M.:

| | | | |
|---|---|---|---|
| Toast..... | | | 80 calories |
| Butter..... | 15 gm. | ½ oz. | 100 calories |
| Cereal..... | 90 gm. | 3 oz. | 100 calories |
| Cream..... | 60 gm. | 2 oz. | 120 calories |
| Milk sugar.... | 15 gm. | ½ oz. | 60 calories |
| Total calories..... | | | 2950 |

By the gradual addition of different foods the fuel value is raised after a few days to 4,000 calories, as follows:

| | | | |
|---|---|---|---|
| Milk..... | 1500 c.c. | 1½ qts. | 1000 calories |
| Cream..... | 420 c.c. | 16 oz. | 480 calories |
| Milk sugar.... | 70 gm. | 2⅓ oz. | 280 calories |

In seven feedings at 9 A.M., 1, 3, 7, 10 P.M., 1 and 4 A.M., each feeding to consists of:

| | | | |
|---|---|---|---|
| Milk..... | 180 c.c. | 6 oz. | |
| Cream..... | 60 c.c. | 2 oz. | |
| Milk sugar.... | 10 gm. | 2½ drams sugar sol. | |

At 7 A.M.:

| | | | |
|---|---|---|---|
| Egg (one)..... | | | 80 calories |
| Toast (one slice) | | | 80 calories |
| Butter..... | 15 gm. | ½ oz | 100 calories |
| Coffee..... | | | |
| Cream..... | 60 c.c. | 2 oz | 120 calories |
| Lactose..... | 15 gm. | ½ oz. | 60 calories |

At 11 A.M.:

| | | | |
|---|---|---|---|
| Egg (one)..... | | | 80 calories |
| Toast or bread | | | 180 calories |
| Butter..... | 15 gm. | ½ oz | 100 calories |
| Mashed potato | 15 gm | ½ oz. | 15 calories |
| Custard..... | 120 gm. | 4 oz. | 250 calories |
| Coffee..... | | | |
| Cream..... | 60 gm. | 2 oz. | 120 calories |
| Lactose..... | 15 gm | ½ oz. | 60 calories |

At 5 P.M.:

| | | | |
|---|---|---|---|
| Egg (one)..... | | | 80 calories |
| Cereal..... | | | 100 calories |
| Cream..... | 60 gm. | | 120 calories |
| Applesauce.... | 30 gm. | | 30 calories |
| Tea..... | | | |
| Cream..... | 60 gm. | | 120 calories |
| Lactose..... | 15 gm. | | 60 calories |
| Total calories..... | | | 3770 |

For still higher values we give the following 4,500 calories:

| | | | |
|---|---|---|---|
| Milk..... | 1260 c.c. | | 860 calories |
| Cream..... | 420 c.c. | | 840 calories |
| Milk sugar.... | 105 gm. | | 440 calories |

This is given in seven feedings, 9 A.M., 1, 3, 7, 10 P.M., 1, and 4 A.M. By doubling the bread, butter, cream, and milk sugar in the foregoing table, 4,500 calories may be given.

In the majority of cases 4,500 calories is a sufficient quantity, but higher feedings may be used if thought best. In private practice the hours for feeding will be changed, as it is not necessary to get started so early as in hospital routine work.

In private practice, also, circumstances may be such that we find it impossible to give solid food; owing to refusal on the part of the patient, or perhaps on the part of the family, we must confine ourselves to fluids, and high values may be given according to the foregoing tables. Where milk disagrees, as it sometimes does, or where it appears as curds in the stools, values may be kept up upon some such diet as the following:

| | | | | |
|---|---|---|---|---|
| Malted milk..... | 7 oz. | 4, 8 A.M., 8, 10 P.M. | 28 oz. | 300 calories |
| Cream..... | 1 oz. | | 4 oz. | 240 calories |
| Malt soup..... | 7 oz. | | 28 oz. | 600 calories |
| Cream..... | 1 oz. | 11 A.M., 6, 9, 12 P.M. | 4 oz. | 240 calories |
| Milk sugar..... | ½ oz. (10 gm.) | | 40 grams | 160 calories |
| Milk peptonized. | 7 oz. | 10 A.M., 4 P.M. | 14 oz. | 280 calories |
| Cream..... | 1 oz. | | 2 oz. | 120 calories |
| Milk sugar..... | ½ oz. (10 gm.) | | 20 grams | 80 calories |
| Coffee: | | | | |
| Cream..... | 2 oz. | | | 120 calories |
| Lactose..... | ⅓ oz. (10 gm.) | | | 40 calories |
| Beef juice..... | | | | |
| Junket..... | | 12 M. | 3 oz. | 200 calories |
| Coddled egg..... | | 1 P.M. | | 80 calories |
| Ice cream..... | | 2 P.M. | 5 oz. | 520 calories |
| Barley jelly..... | | | 3 oz. | 100 calories |
| Cream..... | | 5 P.M. | 2 oz. | 120 calories |
| Lactose..... | | | 10 grams | 40 calories |
| Eggnog..... | | | 7 oz. | 140 calories |
| Cream..... | | 3 P.M. | 1 oz. | 60 calories |
| Lactose..... | | | 10 grams | 40 calories |
| Beef broth..... | | 2 P.M. | 8 oz. | 60 calories |
| Total calories..... | | | | 3540 |

I have collected twenty-nine cases occurring on the Second Division of Bellevue Hospital, during the summers of 1911 and 1912, and my results are based on an analysis of these cases.

The *quantity* of food taken is of great importance, and depends upon the requirement of each individual case; every patient should be given as much as he will take and digest without being forced; aversion to food is often dependent upon lack of variety, and a person will often be tempted by liberal feeding when milk would be declined; nausea, vomiting, distention, diarrhea, undigested milk in the stools, all call for a change of feeding if they are present. Considerable skill is required for the successful feeding of high fuel values, for all patients can not be fed alike, and the prejudices of health remain in disease; feeding can be best done by a skilled nurse who is constantly at the bedside, who prepares the food, who knows the likes, dislikes, and whims of the patient, and who can provide the proper fuel values; if a skilled nurse is not available, the physician must himself oversee the feedings, and reckon daily the caloric value of the food taken.

*Weight.*—The loss of weight depends, generally speaking, upon the amount of food taken; under the old period of fluid diet, patients lost from 15 to 25 or more pounds during their illness; but with sufficient food the loss is rarely more than 10 pounds in severe cases; in moderately severe cases the loss is slight, and not infrequently patients will gain weight. As examples of this maintenance of weight, one patient lost 5 pounds in a febrile period of forty-four days; another, during the relapse of a fifty-three-day period gained 3 pounds; another lost 2 pounds in the relapse of a fifty-five-day period; one gained 6 pounds during a febrile period of thirty-eight days; another lost 3 pounds in a twenty-one-day period; these losses are all insignificant. Most patients will show considerable loss before coming under observation, but after the diet is established the weight can be held within a few pounds in practically all cases, and when allowed out of bed, all patients weigh considerably more than on admission.

*Vomiting* seldom proves a contraindication to the feeding of high fuel values; if any article prove to be distasteful, the patient will soon complain of it and it can be stopped; if vomiting continues the diet is to be stopped until the stomach is quiet and

then resumed; one of my patients took and enjoyed 3,500 calories after suspension of food for vomiting. Severe and persistent vomiting from intoxication makes a different complication, as patients vomit frequently, either everything taken, or else vomit often and seemingly regardless of any particular article. We had one man severely ill and of prolonged course, who vomited frequently but not always the same article of food, and was as apt to vomit water as anything else; this patient was vomiting before admission and it was not due to indiscretion in feeding but to toxicity; he finally died after an illness of fifty-three days, vomiting until the end. Toxic vomiting is always a bad sign and augurs trouble.

*Diarrhea* is not common; it may be due to an excess of fat which can be easily stopped.

*Distention,* if due to milk sugar, is not relieved by the ordinary means, so the sugar can be reduced; these conditions are not common, however, as patients get accustomed to fat and milk sugar and take and handle them well.

*Hemorrhage.*—In the twenty-nine cases cited here there were four cases of hemorrhage, two of which were large and fatal; one of these was an alcoholic subject who had delirium tremens on admission. Hemorrhage occurred in 11 per cent. of Coleman's cases, only one dying, however; to quote Coleman's opinion of hemorrhage, "If the patient be in good nutrition the loss of blood affects him no more than it does a healthy man."

*Relapse.*—Rudisch[10] found the number of relapses to be 8.4 per cent. among 974 cases, prior to the time of high calory feeding. Kinnicutt, in an examination of 600 liberally fed, found relapse no more common than with a low diet which is variously estimated at from 8 to 12 per cent. Coleman[9] had 20 per cent. of relapses among his 111 cases from the Second Division of Bellevue Hospital, but upon investigating the number on the other divisions of the hospital for the same time found these to be 26 per cent., so he concludes that high caloric feeding has but slight influence on the incidence of relapse. My own feeling is that it makes but little difference; cases liberally fed and those lightly fed, seem to relapse equally; there were four relapses in my twenty-nine cases.

*Perforation.*—I had no cases. Crohn reported none in the Mt. Sinai cases. Coleman had one in 111 cases.

*Convalescence.*—Crohn[11] reports that the cases treated at Mt. Sinai Hospital, New York, were allowed to sit up in bed the day the temperature struck normal, and that one or two days after this they were allowed up in a chair; that ten to fourteen days after reaching normal they were discharged from the hospital. I have had no experience with such short periods of convalescence as this, but I do know that the time is shortened and the tedium much relieved. I can not see that liberal feeding makes any difference in the duration of the illness; we had cases of thirty-eight, forty-four, forty-six, fifty-three, and fifty-five days' duration, fed from 3,500 to 4,500 calories.

Of complications other than those named above, there was one phlebitis and one cholecystitis.

*Mortality.*—In speaking of this subject I can do no better than quote Coleman's figures of the cases occurring in Bellevue and allied hospitals from 1907 to 1910 inclusive. There were 102 cases liberally fed with a mortality of 10.7 per cent., there were 773 cases fed otherwise with a death rate of 16.5 per cent. These cases all occurred during the same years and were taken from the same institutions, drawing the same class of society. Of my twenty-nine cases, three died, approximately 10 per cent.; of these one died of hemorrhage, one other also died of hemorrhage who was alcoholic and who was on a low calory diet only; one died who had persistent vomiting both before and after admission, and who had but little feeding of any kind.

*Conclusions.*—The feeding of high fuel values show a cleaner, moister tongue, more comfortable mouth, less offensive breath, less emaciation, less nervous exhaustion which was shown by continuous muttering and constant picking at the bedclothes, a cleaner, healthier skin, greater comfort, less diarrhea, probably lessened mortality, and fewer complications. The most evident features of the high calory feeding, are the sustenance of weight and nutrition, and the amelioration of hunger, and the lessened tedium of convalescence.

## GRADUALLY DEVELOPING HEMIPLEGIA DUE TO A CEREBRAL NEOPLASM.

BY M. HOWARD FUSSELL, M.D.,
AND
SAMUEL LEOPOLD, M.D.
PHILADELPHIA.

THE focal symptoms of brain tumor usually develop gradually. This may occur even when the cardinal symptoms are all absent. The following case illustrates a little-known symptom complex, frequently diagnostic of brain tumor.

The patient, M. M., about six weeks before her admission to the hospital complained of numbness and loss of power in the middle and ring fingers of her left hand. This was followed one week later by a spasm in the left arm and some loss of power, which gradually increased. A little later she complained of pain in the thigh and weakness in the lower limb. At the time of admission to the hospital the left arm was paralyzed and the left leg was weak, though she could drag the limb in walking around the ward. The paralysis gradually increased in the lower limb until she was compelled to remain in bed.

One week previous to her admission she complained of headache. The eye grounds were normal. Her previous medical history showed that she had had a complete hysterectomy one year before.

*General Examination.*—Well-nourished woman, no enlargement of the glands, heart dullness normal, no murmurs; lungs normal. Pupils equal, react to light and accommodation, no palsies of the ocular muscles. The left side of the face is smoother than

the right. Does not draw up the corner of the mouth so well on the left. There is no anesthesia of the face. The left arm is completely paralyzed. She can move the left leg but very slightly. Biceps and patellar tendon reflexes are exaggerated on the left side. Babinski sign is obtained on this side. There is slight analgesia of the left arm and leg. Patient is somewhat drowsy and complains of her head.

Repeated examinations extending over a month failed to reveal any other symptom save that the left-sided paralysis was more complete. The eye grounds remained normal.

She was trephined over the right Rolandic area. No sign of a tumor could be found. Following the operation the patient gradually became emaciated and died several weeks later. An eye-ground examination during this time showed some choking of the discs.

At necropsy the brain showed no evidence of tumor in any portion of the surface of the right hemisphere. The dura at the site of the operation was widely separated and the tissue beneath showed some softening and exudate.

After the brain had been hardened in formalin solution no changes were noted on the horizontally cut surface, with the exception of a small area of softening near the lateral ventricles on the occipital lobe. Portions were taken for microscopical study from this area and from the right Rolandic area just beneath the site of the operation. These areas showed epithelial cells arranged in nests sharply defined from the brain tissue. The diagnosis was adenocarcinoma; probably secondary from the fact that it was multiple.

In a study of this case we find that the chief feature was a gradually developing hemiplegia, extending over a period of several months. In its onset the sudden involvement of the various portions of the upper extremity resembles a thrombotic process.

The cardinal symptoms of tumor, choked disc, and vomiting were absent during the first months. Headache occurred only late in its course, while choked disc did not come on until after operation, and about one month before death.

T. R. Williamson, in 1904, first called attention to the fact that progressively developing hemiplegia was an important sign of brain tumor. In his paper he states that it is well known that when hemiplegia is produced by a brain tumor situated in the motor cortex or white matter of one cerebral hemisphere, the onset of the paralysis is gradual. The movements of one portion of a limb becomes weak, the weakness increases steadily. It may be weeks or a few months before the paralysis is complete. "Headache, vomiting, and double optic neuritis are also present. In such cases, provided there are no indications of suppurative disease in any part of the body and no indication of cerebral abscess, the diagnosis of cerebral neoplasm is certain. But it is not so well known that progressive hemiplegia of the nature just described is an almost certain sign of cerebral tumor, even in the absence of optic neuritis, headache, and vomiting, provided there are no indications of abscess." He reported three cases. In the first case, the person suffered with headache and vomiting for six months previous to her admission in the hospital. The paralysis began in the leg and extended to the arm. Three months elapsed before the paralysis was complete. Optic neuritis was absent. Drowsiness was present.

In the second case vomiting and headache were absent until a month before death. Optic neuritis was absent. The mental condition was peculiar.

The third case showed no headache, vomiting, or optic neuritis. Drowsiness was marked. Only one case of the three showed an absence of all the cardinal symptoms.

In 1908 Souques reported a case of gradually developing hemiplegia with absent cardinal symptoms.

This symptom complex may be present in several other conditions, according to Spiller, who believes that Williamson has expressed his opinion too forcibly. In 1909 he called attention to this syndrome and commenting on it, he states, "A gradual developing hemiplegia I have seen as a symptom of polioencephalitis. Cortical meningitis may cause a gradually developing hemiplegia, and the meningitis may be purulent or of other type." He also reported three cases of gradually developing hemiplegia due to tumor.

Spiller has also seen thrombosis of the middle cerebral artery cause a gradual increase in the symptoms as seen in tumor, but usually when thrombosis is the cause, the development of the symptoms is more rapid.

One of us has recently seen a case of gradually developing hemiplegia in which the hysterical manifestations obscured the diagnosis. It was not until several months after the onset of the symptoms that a slight blurring of the eye grounds presented evidence of increased cerebral pressure.

Slight clouding of the consciousness or drowsiness seems to be present in most of the cases which showed a gradually developing hemiplegia. Of pathological interest was the fact that no tumor could be detected grossly, and that only after microscopical studies were made could the diagnosis be confirmed. The presence of two nodules in separate areas of the brain indicated the metastatic character of the growth. The carcinoma cells were arranged in nests which were sharply defined from the surrounding brain tissue. The nodules were subcortical, which explained the absence of any surface changes.

## STATE CARE FOR MENTAL DEFECTIVES.

By MARIA M. VINTON, M.D.,

EAST ORANGE, N. J.

At a recent meeting of the pediatric section of the Academy of Medicine, the subject of the care of mentally defective persons was discussed. Dr. Charles L. Dana presented the plan of a State Commission for Defectives, similar to the Commission in Lunacy of the State of New York, having powers which shall enable it to bring about suitable care and segregation for defectives, thus preventing the increase of the defective by reproduction. It was stated that the number of mentally defective persons to be found in New York State alone at the present time is about 30,000, of whom 4,000 are under proper supervision. After several interesting papers had been read the subject was discussed, Commissioner of Charities Hebberd and Mr. Angus Thorne, of the Department of Charities, entering into the discussion. These gentlemen advocated care of defectives by the Department of Charities of city and State, saying that the matter could be best handled in this way, with the assistance of special legislation to aid in obtaining legal control of these unfortunates.

It appears to the writer that such control could

be exercised by the Department of Charities and the State Board of Charities only in so far as the mentally defective children, or adults were from the poorer classes, whose relatives are unable to care for them in their homes, and are obliged, however unwillingly, to place them in institutions. The first great obstacle to the care of mentally defective children would be presented in the fact that the words "Department of Charities" or "State Board of Charities" would be a sufficient reason among most taxpayers for a refusal to place their children under such care. The writer has been a medical school inspector under the New York Health Department for some fourteen years, meeting these children during all of that time, and having studied the question for over two years with reference to two ungraded classes in the public schools of Woodhaven and Richmond Hill. These towns are located in the Borough of Queens, just outside the Brooklyn city line. Richmond Hill is occupied by the families of business men who travel daily to Manhattan for their business. It is not at all uncommon when the medical inspector of the Health Department employed in the schools sends home a note requesting treatment for some physical defect, or some contagious skin disease, to receive a note stating that the parents have no need of the services of the medical inspector, and will thank her to mind her own business. Should the words "Randall's Island" or "Department of Charities," with reference to the care of a mentally defective child in Plublic School No. 90, where one ungraded class is located, be so much as spoken it would call forth a storm of protest from the parents, and the statement that they are taxpayers, abundantly able to support and care for their children, and would scorn to accept assistance from city or State. This statement would be quite true. It would seem that the gentlemen who are constantly employed in administering the city charities have forgotten the attitude of the mass of citizens of New York, with reference to "the Islands," and the acceptance of city money as a charity. However much the citizens may be desirous of obtaining those moneys in the way of graft, they are not desirous of accepting them as charity. This is simply an example of the condition which obtains in all towns outside of our great metropolis. Except among the very poor, a family having a mentally defective child will strain its resources, if need be, to place the child in a private institution rather than in a public one. A few examples personally known to me will show the social position of some mental defectives. I have a personal knowledge of two such persons maintained in private institutions who are children of professors in prominent colleges, one the son of abundantly wealthy parents. Neither of them could be allowed at large without peril to themselves and the community. Imagine an attempt to place these two boys under the care of the State Board of Charities! Nor would it be just to so place them. The care which their parents are able to obtain for them in private institutions is far better and far different from that which could be given them under a board of charities. Thus, it would seem at once that we must have a board that has not the hated word "Charities" in its title, if we are to secure the cooperation of the mass of the public, either in city or country. In a small town care by a board of charities is generally administered by the overseers of the poor, or at the almshouse. It is considered a public disgrace to get into the hands of either class of officials.

Another reason for not placing these unfortunates under the care of a board of charities is that it is the manifest duty of such a board to care for the poor only, allowing the better off "taxpayer" to maintain at his own expense the unfortunate members of his own family. The State should not be burdened with such an expense as the care of 30,000 mental defectives would entail. The greater part of the expense outside the large cities should be borne and would gladly be borne by the private individual. But it is necessary that we have some central authority which will be able to use authority and legal force where it is necessary to bring the mental defective under proper care. It takes the parents of some high-grade defectives, and they are the defectives who are dangerous to society, several years of schooling for the child in a graded class to convince him that mental defect exists, and that the special care of an ungraded class is necessary to develop his mind at all. I have in mind two mentally defective children of a very intelligent member of the city detective force, attached to the Brooklyn central office, who were passed for an ungraded class more than a year ago, and who are still sitting in graded classes because the father cannot be convinced that they need, and would be benefited by transfer to an ungraded class in a public school. It is the opposition of the parents that must be overcome by a centralized authority before we can have even proper education for the mentally defective child, much less custodial care or sterilization.

It appears to the writer that we have need of a much wider campaign of education of public opinion in this matter of the care of mental defectives than is at present being carried on. The expert who has studied this matter, the intelligent physician and neurologist, the advanced social worker are alive to the necessity of custodial care and the desirability of preventing reproduction of the unfit. But the average citizen understands nothing of this and resents any interference in the matter. To him it seems an unwarrantable trespass on the prerogatives of a free citizen of our great democracy to even suggest custodial care for the weaker members of his family. Anyone who has ever worked under a city department knows how hard it is to secure even the most simple changes in the direction of increased hygienic facilities or sanitary reforms in the most enlightened communities without a wide educational propaganda, and sometimes a costly epidemic to point the moral.

For the care of mental defective in the State of New Jersey, Mr. E. R. Johnstone, of the Vineland school, has suggested the following plan: 1. All feeble-minded children from 6 to 12 years of age, except idiots, should be placed in ungraded classes in the public schools the parents thus bearing the expense of feeding, housing and clothing them. 2. In each important city an institution should be established to care for those between the ages of 12 and twenty, which should be under the care of the educational authorities. Here the expense is borne by the municipality. 3. Those over 21 should be cared for at a State institution. 4. All idiotic cases should be cared for in such State institution or in almshouses. This seems to me a feasible plan for the State of New York as well. First of all a State commission to exercise the necessary authority over parents. Then the establishment of an ungraded class in every town, or in every school in a city. If the principals and teachers will educate themselves

in this matter and will carefully sift and classify their pupils, they will generally find material for an ungraded class in any good sized school. Where there are several small schools under one school board, one ungraded class may be enough among them all. From 12 to 20 years of age each municipality can establish a home under the educational authorities in which the remaining young people can continue their educational training. Next, State institutions, Letchworth Village, Craig Colony, or a newly established institution for mental defectives can care for the older ones and the idiots.

New York City, with its well established system of ungraded classes in schools, due to the untiring work and zeal of Miss Elizabeth Farrell, can well take care of all but the very low grades, those being sent to Randall's Island. The writer saw in an ungraded class this week a Mongolian idiot of some six years growth who was quite unable to enter into any of the class work, and was simply a burden to the teacher. State control could have forced his parents to place him on Randall's Island and thus have made a vacancy in the class for one of the three children on the waiting list of that ungraded class.

For the reasons here elaborated the writer would submit that no satisfactory control over mental defectives can be exercised by boards of charities, and that a central authority, such as a State commission, is absolutely necessary to exercise the desired authority over the parents. The expense of such care should be borne by the parents, the municipality and the State jointly, according to the age and degree of mentality of the patient, and the financial standing of the parents. All that can be done in the way of education can be done by the regular school authorities. Lastly, let us at once begin, through public health education committees, medical societies, social clubs and other agencies, a widespread campaign of education of the public in the line of educational and custodial care and segregation of mental defectives.

15 Halstead Place.

## THE MEDICAL TREATMENT OF APPENDICITIS.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

The following is an earnest plea for great conservatism, as opposed to the prevailing, and as I believe, erroneous judgment of frequent operations almost as soon as the diagnosis is made. The rules of medical treatment given by me are, in my opinion, eminently judicious and safe, but especially so, for all travelers in localities in which experienced surgeons and modern hospitals are not found.

Rest on back in bed. Liquid food; enemas of warm water and sweet oil to move the bowels. (Mix oil with yolks of egg, add water and stir.) Use plenty of oil—6 to 8 tablespoonfuls not too much. Give enemas with fountain syringe (preferably) or Davidson's syringe, with the patient on the left side, near the edge of the bed, the knees drawn up; retain the enema a little while unless there is much griping or increased pain. In that case let the enema come away and repeat later. Give from a pint to a quart, or more, of liquid with each enema, to wash out the lower bowel thoroughly. It is desirable to attach to the metal or hard rubber tube of the syringe a short soft rubber tube about six inches long and half inch caliber for enemata. Before introducing the tube into the bowel see that the air is expelled and that liquid is coming out of tube.

Apply locally over the belly, warm flannels wet and wrung out with alcohol and water (one part alcohol, three parts warm water). Cover the wet flannel with rubber tissue. When the flannel is dry wet it again with alcohol and water.

Give codeine tablets, grain 1/10, every two hours until the pain is notably less; then less frequently.

There must be no transport from the bed or sitting up, so long as pain in the belly continues and even if there be little or no fever.

Give cracked ice and the best brandy for nausea or weakness, a teaspoonful frequently. Give the best and most nutritious liquid foods, *i.e.* strong broths or milk alternately or mixed together. Of these, one or more ounces every two hours should be given, when prostration is present. These would preserve life for many days.

Operation is absolutely forbidden during the acute period, unless a good surgeon is present and the conditions for operation are favorable. In the vast majority of cases a "cure" will be established in several days. Later on, in the interval or quiescent period, operation may be indicated, when the patient seems practically well, except for the experience of the acute attack. Operation may be done then at home or in a modern hospital.

42 West Thirty-seventh Street.

## Medicolegal Notes.

**Provision for City Bacteriologist.**—The Washington statutes provide for the creation of city boards of health, but the provisions are not to apply to any city in which a board of health is organized and a health officer appointed under a special charter. The charter of Spokane provided for a board of health, and an ordinance of February, 1910, provided for the appointment by the board of a bacteriologist. One was appointed. In December, 1910, the city adopted a new special charter, not providing for any board of health. The mayor then notified the bacteriologist that his services as such were at an end. He commenced an action to compel his reinstatement. It appeared that a new bacteriologist was appointed by the city to succeed him, employed, it was presumed by the court, by the board of health subsequently organized under the general laws of the State. It was held that the new charter repealed the old charter provisions for a board of health, and that the ordinance providing for a city bacteriologist was abrogated. Two judges dissented, on the ground that the appointment of a bacteriologist to succeed the complainant precluded the city from asserting that the office did not exist under the new charter.—State v. Hindley, Washington Supreme Court, 121 Pac., 447.

**Insurance—Proofs of Death.**—In an action on a policy of life insurance it appeared that the application for insurance contained a representation that the deceased had consulted no doctor or had any ailment within five years of the date of the application, except that she had consulted a physician for grippe three years before. After the death of the insured, the beneficiary filed as proof of death a certificate from the attending physician stating that the immediate cause of the death of the insured was chronic nephritis and chronic hepatitis. After this certificate was filed, the insurance company sent the beneficiary a blank certificate, also entitled "Proof of Death," with the request that she have it executed by a certain Dr. Chapman, who, it appeared, had previously attended the insured. The beneficiary requested Dr. Chapman to execute this certificate, and the latter filled in the blanks, verified the certificate, and returned it to the beneficiary, who filed it with the insurance company. The certificate contained the statement that the affiant had on two occasions treated the insured for nephritis within two years of the signing of the application, thus contradicting the statement in the application. It was held that the beneficiary by her action had not only made Dr. Chapman her agent, but had ratified his authority by filing the certificate. His statement was, therefore, binding on her.—Leonard v. John Hancock Mut. Life Ins. Co., 135 N. Y. Supp. 564.

## THE THERAPEUTIC DILEMMA AND ITS PSYCHOLOGICAL BASIS.

WITH the increasing precision in diagnosis and treatment characteristic of modern medicine, there is a correspondingly diminishing reliance on the expectant method of combating disease. The doctrine of *laissez faire* in political economy has furnished a seductive analogy to the passive attitude of those who would place an undue emphasis upon nature's own curative powers. The secret of therapeutic success lies in appreciating when to interfere and when not to interfere in the natural evolution of a pathological process. The problem, in brief, is one of individual judgment. Upon this supreme mental faculty success in the practice of the healing art ultimately depends. The wealth of knowledge gleaned from the stores of a world's literature cannot take the place of that practical experience which is valuable in proportion as it develops the power of discrimination.

In spite of the exercise of this rare gift, the clinician is frequently compelled to halt in the presence of a problem which even his ripe experience will not enable him to solve. Two courses of action may be open. Yet different decisions will be rendered by men of similar experience and professional standing. This difference of opinion may be attributed to the imperfection of medicine as a science. Nevertheless, there are instances in which two different sets of indications may be present in an individual case. A consultation between men of nearly equal eminence may lead to the discovery of one or more facts which will throw added weight on one side of the dilemma and this course of action is then decided upon.

Instances of this duality of therapeutic indications will readily suggest themselves to every practitioner. They arise in the practice of general medicine, of surgery, and of the specialties. Thus, during the course of an acute otitis media, the drum membrane may be highly inflamed though not bulging, and there may be evidence of the presence of fluid in the tympanic cavity. Yet there may be a difference of opinion among otologists of equal experience as to whether it is necessary or not to perform myringotomy. Some will advocate early incision of the drum membrane as a safe measure in miminizing the possibility of complications. Others will counsel waiting, at the same time that the patient is closely watched so that if the inflammatory symptoms do not subside under local and constitutional revulsive treatment, or if bulging of the tympanic membrane occurs, there can then be no question as to the necessity of performing paracentesis. Similarly the problem may arise whether in a given case of mastoiditis it is wise to wait for spontaneous recovery or whether it is safer to operate. Fortunately with the newer methods of laboratory and *x*-ray examination this problem is not as difficult as it was several years ago, nevertheless, one may cite instances of mastoid operations needlessly performed and at the same time instances of fatalities that might have been avoided by a timely operation. In general, the dictum: "When in doubt, operate" holds true here as in other branches of surgery.

The circle of those who counsel waiting in the presence of a case of appendicitis is fortunately growing smaller and smaller. The insidious nature of this disease and the fact that clinical signs may fail to reveal the exact condition of a morbid appendix, point to the operative treatment as the only safe one. Nevertheless, this need of surgical intervention increases the responsibility of the surgeon in ruling out other causes of pain in the right iliac fossa, for the instances are not few in which a case of Henoch's purpura or of pneumonia has been mistaken for one of appendicitis.

The obstetrician is confronted with his own set of dilemmas. One may cite an example in the two attitudes with respect to the management of a case of occipito-posterior presentation of the vertex. There are many accoucheurs of experience who will give the natural forces of the patient an opportunity to rotate the occiput to the front. On the other hand, there are those of equal eminence who counsel early interference—who advocate a forcible manual rotation of the child's head as soon as the cervix will admit the hand of the obstetrician. Which course shall be pursued is dependent largely upon the skill of the latter in accomplishing what may be an extremely simple procedure in experienced hands. Nevertheless, the average general practitioner will prefer to give nature a chance in effecting, at least in some of these cases, a spontaneous delivery.

It is unnecessary to multiply examples of the dilemma in therapeutics. There are certain psychological elements that must be understood if one would correctly gauge the difficulties in these cases. It is impossible to eliminate from the discussion of this subject the question of the personal factor of the physician himself. A recent disastrous result of the so-called expectant treatment may be the cause of an attitude of timidity on the part of the physician or may determine an early operative interference on the part of the surgeon. There are alarmists in the healing art who look on the darkest side of every case, and there are, at the same time, those whose optimism may blind them to important danger signals. The happy mean between the conservative and the radical is, after all, the rarest attainment in the mental equipment of the physician.

It is important that every one who aspires to treat his fellow man should know his own limitations. These may be a lack of scientific knowledge or manual dexterity, a natural timidity or daring, an unreliability of judgment, an overweening self-reliance, or a lack of confidence in one's own powers. With this realization of the personal factor, the solution of the therapeutic problems that present themselves is greatly facilitated, for the ultimate decision may then be tempered or modified by the knowledge of the personal bias that influences the judgment, if only to a slight extent.

The most important means of narrowing the circle of the therapeutic dilemmas is the extension of scientific knowledge. In the treatment of disease there can be only one "strictly right" method. So-called alternative methods either are identical or of different degrees of merit, or they may all be wrong. The last is more apt to be the case when the methods of treatment are particularly numerous. The sharper demarcation of the etiological factors in disease causes a corresponding limitation of the methods of treatment. However exact one's knowledge of disease may be, this knowledge cannot take precedence over good judgment. "Knowledge comes, but wisdom lingers."

## THE ROLE OF WOMAN.

In these days woman is very much in evidence. In this country, more than in any country, she has taken a definite place in industrial and professional life, and there are now few pursuits in which she does not compete with man. In Great Britain, although women are not so conspicuous as wage earners, they are more prominent by far in the field of politics, and have become a force to be reckoned with by statesmen. Some think that they have gone out of their proper sphere, and that they and the race at large will suffer by the departure from long-held customs and habits, while others are of the opinion that it is beginning to be recognized that they were not intended for domestic life alone, but have the right to be put on the same plane as men. The actions of the suffragettes in Great Britain certainly seem to favor the view that they are not altogether fitted for the responsibilities of life, but be this as it may, it is obvious that we must revise our views as to the rôle of woman. In America, at any rate, the rôle of woman is surely entirely different from what it was comparatively few years ago. In industrial pursuits, in numbers women almost rival men, and from the economic standpoint the change has brought about radical results, whether for good or evil it is hard to say.

In a medical journal it is from the point of view of health and of the good of the race that the question is to be considered, and here we appear to stand on fairly firm ground. Considered from this aspect, the wholesale employment of women is an unmitigated evil. It goes without saying that if women refuse to bear and bring up healthy children they will not fulfill their physiological duty, and the nation must suffer. Woman's participation in industrial occupations has during the past decade effected great transformations, which have not tended to the advantage of her productive and reproductive strength. In short, industrial and professional work, to a great extent, unfit a woman for motherhood and domestic life, as is plainly shown by the unwillingness of the present generation of women to undertake the duties of motherhood and home. In addition it is distinctly against the interests of the race, mentally and physically, that a mother should engage in outside work. Infants should be breast fed, which is impossible if the mother is working away from home; when young they should be constantly under the eye of the mother for the sake of their physical, mental, and moral health, and if this is not done they, and ultimately the race, will suffer harm. At the present time a lamentable waste of women is going on, and the matter requires immediate attention. The fact must be recognized that the rôle of woman has changed, that this change is not for the better—at least, not from a medical point of view, and while allowing that the old state of affairs has gone, never to return, at the same time steps should be taken to endeavor to deal with existing conditions in such a manner that the race will suffer as little as possible. A necessary movement in this direction is to find out exactly how matters stand by initiating measures for the compilation and publication of national and international statistics relating to the participation of women in industrial pursuits.

## A CIVILIZATION-WIDE WARFARE.

For several years past fly extermination has been essayed, on the basis of this insect's now well understood germ-conveying proclivities. Americans, being a people much moved by slogans, "Swat the Fly" is one which has excited a vast deal of industry, with somehow not very appreciable diminution in the number of flies. With a better understanding of the conditions the wiser slogan "Starve the Fly" has supplanted the other. As we have repeatedly said, it is vastly more to the purpose to destroy the breeding places of flies and their filthy pabulum than to kill individual insects while the filthy lying-in chambers of mother flies are permitted to exist.

This year the antifly campaign is already on, it being recognized that hibernating mother flies, which may be fecundated, must be destroyed before April, when they would have an opportunity to lay the season's initial batch of eggs. To begin thus early would seem to be a logical step, since it has been computed that one over-wintering mother fly could (mathematically at least) found a tidy genealogical tree which would, by the end of the fly season, amount to several billions of branches, twigs, and budlets.

The Bureau of Entomology in the Department of Agriculture at Washington is ready to furnish to all citizens detailed information as to the procedures which should obtain. The Fly Fighting Committee of the American Civic Federation, in New York City, is also ever ready to be of service, and its literature has been requested and sent not only throughout these United States but also to France, England, Italy, Ireland, India, Egypt, the Philippines, Korea, Australia, Hawaii, Singapore,

Venezuela, and other regions. This association has for years worked for agitation, education, and organization against the fly. Mr. Edward Hatch, Jr., its president, arranged for the manufacture of the gruesomely-fascinating film entitled "The Fly Pest," which has been shown in moving picture halls and "nickelodeons" throughout the country. Lantern slides illustrating the subject are loaned to responsible persons applying to the committee in New York. A traveling exhibit, consisting of photographs and placards warning against the fly, is also to be had of this committee by local organizations. It urges the individual worker against the fly to interest his neighbors, so that they may cooperate with him in the antifly propaganda. The lay press will no doubt, as heretofore, give support. Fly ordinances should be framed. Civic societies, labor organizations, women's clubs, granges, and churches should become active in this good work. Prizes may be offered under the auspices of boards of education to school children uniting on "The House Fly as a Carrier of Disease." Hotel and restaurant keepers and factory owners should certainly become interested.

The part which the fly plays in the transmission of the bacteria of tuberculosis, typhoid fever, "summer complaints," and infectious dysenteries, has now long been known, and need not be dwelt upon here. With regard to the filth, it should be recalled that upward of ninety per cent. of fly-breeding takes place in horse manure; this fact should of course not lead to the neglect of the spittoon, the garbage can, the unclean dairy, the putrescent animal in the public streets and gutters, and the privy.

---

### "Isolated" Mental Inferiority.

No subject is more puzzling to-day than the great variability of type of psychopathic children. While the superior imbecile or debile, the degenerate, and others are tolerably constant in their characteristics, there are many types of childhood in which some one peculiarity stands out strongly as the chief evidence of psychasthenia, while of more or less prominence are minor aberrations. We may select the case of a boy with harmless imperative concepts and tendency to the formation of useless habits, who is also obsessed with the idea that certain people look down upon him because he works with his hands. The same individual is unable to eat some of the most natural of food substances. "Odd," "notional" children and adolescents very often outgrow all these peculiarities or at least become able to suppress them; and in general unless the mental state shows a progressive tendency to retrograde we should not be in haste to class these individuals as defectives. It is otherwise when a normal subject shows a positive defect along a single line, and at a recent meeting of a Wisebaden medical society (*Berliner klinische Wochenschrift*, February 17) Vogt described one of these rare examples who was technically neither debile, degenerate, nor psychasthenic. The age was but eleven years and the boy was unusually bright, yet had never mastered reading or writing. He drew well, and had a good notion of mechanical draftsmanship. Some organic defect might be suggested, but "soul blindness" in the ordinary sense of the term could be absolutely excluded. The boy was simply unable to commit letters into words. All other tasks suitable to his age he mastered easily.

---

## News of the Week.

**State Health Bill.**—On March 12, Governor Sulzer of New York transmitted to the Legislature with a special message, a bill providing for the reorganization of the State Department of Health in accordance with the recommendations of the Commission appointed by the Governor last January. The bill gives the State Commissioner of Health the power to take charge of local affairs when no health officer is chosen, provides for the abolition of town and village boards of health and the transfer of their duties to town and village boards of trustees, divides the State into sanitary districts under the supervision of sanitary officers paid by the State, extends the power of the department over tenement houses in all cities, requires the health commissioner to inspect all State institutions at least once a year, and lays down stringent regulations for the care and disposition of patients with tuberculosis. The Governor in his message says: "This bill is a justice-promoting measure. By its enactment the State would perform in a more nearly adequate degree the imperative duty resting upon it to protect the health of its citizens. This measure, if enacted, would place the State of New York in the front rank of those States in which the people, through their duly constituted representatives, have taken wise and far-sighted action to promote health, vigor and efficiency.

**Experimenting on Insane.**—A bill recently introduced into the New York State Legislature authorizes the appointment by the Governor of a commission to investigate the extent of the alleged practice of experimentation upon human beings, especially children, without their consent in hospitals and other public institutions by inoculations and other treatment or tests not undertaken for the benefit of the individual and having no relation to his individual necessity. It is claimed by the sponser of the bill that at a recent hearing on the antivivisection bills evidence was produced showing that insane patients are often subjected to experiment with serums for the prevention of typhoid fever and other diseases without their knowledge, and that it is necessary to protect these persons by law from injury or interference with their personal rights.

**Medical College Transfer.**—The College of Physicians and Surgeons of Chicago on March 6 became again a part of the University of Illinois, by the formal transfer of the college property to the trustees of the University. The present staff of instructors will be retained at least until the end of the present academic year.

**Inspecting the Canal.**—Under the auspices of the Illinois State Medical Association, a large party of physicians and their families left Chicago on March 2 for a trip to Panama, going by way of Florida with stops at Kingston and Havana.

**Hospital Sold.**—At the sale of the property of the New York Nursery and Child's Hospital held by order of the City last week, the sum of $446.100 was realized, of which 60 per cent. will go to the hospital and 40 per cent. to the City.

**Hospital for Deformities and Joint Diseases.**—Plans were filed recently with the Building Depart-

ment of New York City for the new structure of the Hospital for Deformities and Joint Diseases which will be erected on 123d Street between Madison and Park Avenues. The building will be six stories high, with a frontage of thirty-four and depth of ninety feet, and will be fireproof. It will contain gymnasiums and Zander rooms for both men and women, a room for electric treatments, and an *x*-ray room. The architects have estimated the cost at $90,000.

**New Railroad Hospital.**—The Santa Fé Railroad on March 1 opened a new hospital at Mulvane, Kan., which was built at a cost of $100,000. Dr. Herman W. Goelitz, formerly of Las Vegas, N. M., has been placed in charge.

**Hospital Fire.**—Presumably from defective insulation a fire started in a small storeroom on the top floor of the Har Moriah Hospital, New York, on the morning of March 10, but was extinguished with no results more serious than the filling of the hospital with smoke and the consequent alarm of the patients in the wards.

**Smallpox in Capital.**—The State, War, and Navy Department building in Washington was invaded by the surgeons from the Public Health Service on March 11, and some hundreds of employees of the War and Navy Departments were vaccinated. The discovery of two cases of smallpox in the building was responsible for the wholesale procedure.

**Harvey Society.**—Prof. Franz Knoop of the University of Freiburg, Germany, will lecture before the Harvey Society at the Academy of Medicine, New York, on Saturday evening, March 22, on "Modern Problems of Nutrition."

**Death Rate Up.**—For the week ending March 8, the death rate in New York City was 16.73 per thousand, the total number of deaths being 1,723, while for the corresponding week of last year the rate was 16.21 and the number of deaths 1,608. Pneumonia is given as the cause of death in 375 cases and influenza in 21, these two causes of death being chiefly responsible for the increase. The death rate for the first ten weeks of the year was 15.57 as against 15.63 for the same period of 1912.

**Hospital for Diseases of the Chest.**—The Trustees of Jefferson Medical College have purchased the premises formerly occupied by the Henry Phipps Institute for Tuberculosis at Third and Pine Streets, Philadelphia, and which will be devoted to the treatment of diseases of the chest. There will be accommodations for 52 bed patients and a complete dispensary service will be organized under the direction of the professor of medicine, Dr. Thomas McCrae.

**Canal Zone Report.**—During the month of January, 1913, there occurred 51 deaths among the employees of the Canal Commission in the Canal Zone, of which 32 were due to disease and 19 to violence, giving an annual death rate per thousand of 11.74. This is the highest rate recorded for the month since 1908, when the rate was 12.72. The lowest rate recorded for January was in 1912, when it was 8.10. The death rate per thousand among the civil population was also higher than during the same month last year, being 23.24 as compared with 17.67. Among employees 2 deaths were due to hemoglobinuric fever, 5 to lobar pneumonia, 2 to malarial fever, 2 to organic disease of the heart, 8 to tuberculosis, and 1 to typhoid fever. "No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month."

**American Museum of Safety.**—A children's safety crusade has been carried on in the New York public and private schools since last December by the American Museum of Safety under the direction of Dr. William H. Tolman, and nearly twenty thousand children have enlisted as members of the Safety League. The children are taught by illustrated lectures how to avoid injury in the public streets and are given simple rules for their guidance on the street, in case of fire, and in other dangerous situations.

**Gifts to Charities.**—St. John's Hospital, Brooklyn, receives $1,000, and the Thanksgiving Hospital, Cooperstown, N. Y., $500, by the will of the late Mrs. Mary A. Taffe of Brooklyn.

By the will of the late James H. Sternberg of Reading, Pa., the sum of $10,000 is bequeathed to the Reading Hospital.

By the will of the late Mr. Ferris S. Thompson of New York, who died recently in Paris, the sum of $200,000 is left to the Mercy Hospital, Chicago; the New Bedford, Mass., Tuberculosis Sanatorium receives $10,000, the Woman's Hospital, New York, $25,000, and the American Hospital, Paris, $25,000, all in memory of the testator's mother, while two-fifths of the latter's residuary estate, the value of which is not given, are left to the New York Skin and Cancer Hospital. In addition the will provides that trust funds amounting to $155,000 go to St. Luke's Hospital, New York, and other trust funds amounting to $70,000 to the Woman's Hospital, on the death of the beneficiaries.

St. Joseph's Hospital for Consumptives and St. Vincent's Hospital, New York, receive $1,000 each, and St. Rose's Home for Incurable Cancer and the Hospital for the Blind in the Bronx receive $500 each by the will of the late Thomas S. Bardon of this city.

In the adjudication of the estate of the late Anna H. Carver of Philadelphia the following charitable bequests have been awarded by the Orphans' Court: Trustees of the University of Pennsylvania, for hospital beds; trustees of the German Hospital, for hospital beds; trustees of Jefferson Medical College, for hospital beds, each $50,000; Hospital of the Protestant Episcopal Church, $10,000.

**Medical Society Elections.**—Story County (Ia.) Medical Society.—The following officers were elected at the meeting in Ames on March 6: *President*, Dr. H. Dewey Chamberlain, Nevada; *Vice-President*, Dr. E. B. Bush, Ames; *Secretary*, Dr. Frank S. Smith, Nevada.

Hart County (Ky.) Medical Society.—At the regular meeting held in Munfordville on March 4 the following officers were elected for the ensuing year: *President*, Dr. James William Craddock, Bonnieville; *Secretary*, Dr. Dodson, Rowletts.

Lane County (Ore.) Medical Society.—At the annual meeting held at Eugene on March 1 officers for the ensuing year were elected as follows: *President*, Dr. Omar R. Gullion, Eugene; *Vice-President*, Dr. Beniah R. Job, Cottage Grove; *Secretary-Treasurer*, Dr. Grant S. Beardsley, Eugene.

Llano County (Tex.) Medical Society.—The following officers were elected at the annual meeting held in Llano on February 28: *President*, Dr. Henry S. Selman, Llano; *Secretary*, Dr. Charles F. Darnell, Llano.

**Obituary Notes.**—Dr. Roland G. Curtin died at Philadelphia on March 14 at the age of 74 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1866. Subsequently he served as resident physician in the Philadelphia Hospital and at a later period he was for many years visiting physician to the same institution and for a time president of its Medical Board. He was for eleven years assistant physician to the Philadelphia Lying-In Charity; for ten years chief of the medical dispensary of the University of Pennsylvania, and for six years physician to the throat and chest department of the Howard Hospital. He was also for a time physician to the Hospital of the University of Pennsylvania and to the Presbyterian Hospital, and consulting physician to the Rush Hospital for Consumptives. He was a member of the Philadelphia County Medical Society (and for a term also its president), of the Medical Society of the State of Pennsylvania and of the American Medical Association, a Fellow of the College of Physicians of Philadelphia, a member of the American Climatological Association (also at one time vice-president and later president). He was assistant medical director at the Centennial Exposition held at Philadelphia in 1876 and honorary president of the Medico-Climatological Division of the World's Congress at Chicago in 1893. He received in 1871 the degree of Doctor of Philosophy from the University of Pennsylvania and in 1883 the degree of Master of Arts from Lafayette College. He was naval storekeeper at the Philadelphia Navy Yard during the Civil War.

Dr. John A. Mueller of Dyersville, Ia., a graduate of the State University of Iowa, College of Medicine, in 1892, was almost instantly killed on March 1, when the carriage in which he was driving was struck by an Illinois Central train near Schermer's crossing. Dr. Mueller, who was forty-one years of age, was for several terms mayor of New Vienna, where he formerly resided.

Dr. James F. Lamb of Shelbyville, Ind., a graduate of the Eclectic Medical College, Cincinnati, in 1878, died at his home from locomotor ataxia on February 26, after a long illness, aged 59 years.

Dr. Price W. Atkins of Marion, Va., a graduate of the College of Physicians and Surgeons, Baltimore, in 1875, and a member of the Virginia State and Smyth County Medical Societies, died at his home on March 2, aged 57 years.

Dr. Thomas H. Doyle of St. Joseph, Mo., a graduate of New York University Medical College in 1865, emeritus professor of medicine in the Ensworth Medical College, St. Joseph, a member of the American Medical Association and the Missouri State and Buchanan County Medical Societies, having been first president of the last, and formerly mayor of St. Joseph and a member of the police board, died in St. Joseph's Hospital on February 25, aged 73 years.

Dr. Saul Brock Angle of Windsor, Va., a graduate of the University College of Medicine, Richmond, in 1901, and a member of the Virginia State and Isle of Wight County Medical Societies, died in St. Andrew's Hospital on February 23, aged 32 years.

Dr. Henry William Brown of Waterloo, Ia., a graduate of the Geneva Medical College, New York, in 1867, and a member of the American Medical Association and the Iowa State and Blackhawk County Medical Societies, died at his home on February 27, after a long illness, aged 68 years.

## Obituary.

### JOHN SHAW BILLINGS, M.D., LL.D., D.C.L.

NEW YORK.

Dr. John Shaw Billings, Lieutenant-Colonel, U. S. A., retired, died at the New York Hospital, New York, on March 11, aged 74 years. Dr. Billings was born in Switzerland County, Indiana, and was graduated from Miami University, receiving the degree of A.B. in 1857 and of A.M. in 1860. In the latter year also he received the degree of M.D. from the Medical College of Ohio, Cincinnati. In the following year he enlisted in the Federal army as an assistant surgeon, and after the war was put in charge of vital statistics and made curator of the Army Medical Museum and Library. Here he did much to increase the size and importance of the library of the Surgeon-General's office which now ranks as the third largest medical library in the world, being surpassed only by the library of the Medical School in Paris and that of the Imperial Military Medical Academy of St. Petersburg. He founded the "Index Catalogue" of the Library of the Surgeon-General, editing the first sixteen volumes of the first series. In 1894 he was made a lieutenant-colonel and Deputy Surgeon-General.

From 1894 to 1896 he occupied the chair of hygiene at the University of Pennsylvania, Medical Department, and in the latter year came to New York as director of the New York Public Library, an office which he held up to the time of his death. He was a member of the National Academy and of the American Surgical Association, and was the author of many works on sanitation. He received the honorary degree of LL.D. from Edinburgh in 1884, from Harvard in 1886, from Yale in 1901, and from Johns Hopkins in 1902, and the degree of D.C.L. from Oxford in 1889.

### PRINCE ALBERT MORROW, M.D.

NEW YORK.

Dr. Prince A. Morrow, who died suddenly at his home in this city on March 17, was born in Mt. Vernon, Ky., December 19, 1846, and was a graduate of the New York University Medical College in 1874. He was one of the older generation of dermatologists in America. From 1884 to 1904, he was attending surgeon at the City Hospital. He was first clinical professor of venereal diseases; then lecturer on dermatology, and finally, clinical professor of genitourinary diseases at the University and Bellevue Hospital Medical College. He was consulting dermatologist to St. Vincent's and the City Hospitals. He was a member of the County and State Medical Societies, of the New York Academy of Medicine, American Academy of Medicine, and of the New York Dermatological Society, having served as president of the latter in 1890-91. Dr. Morrow was the founder of the American Society for Sanitary and Moral Prophylaxis, and had served as president since the organization of the Society in 1905. He was an honorary member of many dermatological societies in this country and abroad. Among his numerous contributions to medical literature are "Drug Eruptions," "Atlas of Skin and Venereal Diseases," "A System of Genito-Urinary Diseases," and "Syphilology and Dermatology." At one time Dr. Morrow made a special study of leprosy, visiting the leper colony in the Island of Molokai in order to make personal observations of the disease.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

APPENDICITIS; WHEN TO OPERATE — "DISSECTING VARIX," CASE OF THE LATE DR. W. RIVERS POLLOCK—DEATHS FROM ELECTRICITY—KEITH ON THE UPRIGHT POSTURE—HOSPITAL MEETINGS—OBITUARY.

London, Feb. 28, 1913.

Since the part played by the appendix in abdominal inflammatory cases has been fully recognized and the toleration of surgical interference established operative measures have been extended to nearly, if not all, varieties of attack. At present the question the surgeon asks in a serious case is not so much is operation required as at what period to intervene. There is indeed a small minority of practitioners who hold, more or less confidently, that as many cases of appendicitis recover under simple treatment, the risks of operation should not be run except in urgent cases. Some have even asserted that if all were left to nature the recoveries would be as numerous as if all unquestionably grave cases were subjected to operation. A larger minority are for holding a watching attitude when called to what they consider a mild case. This is a natural view for the family attendant to take considering the position he holds toward the patient and his friends to whom he has to communicate the condition of the sufferer, and to suggest, if he thinks proper, calling in further advice. The surgeon accustomed to operate has, in such cases, only to decide on the prospect of a successful result. This being good, he is ready for the responsibility, knowing that at the best temporizing leaves the probability of recurrence.

A discussion on the subject at the Medical Society of London was opened on the 10th inst., and a full representation of surgical opinion was anticipated. There was, however, no debate, for Sir George Beatson, who had undertaken to defend the temporizing plan, was unable to attend. All the speakers accordingly favored immediate operation. Mr. Edmund Owen, who was to open the debate, is a thoroughgoing advocate of this, and has no hesitation in pronouncing many of the deaths that have occurred as quite unnecessary, inasmuch as if an early operation had been resorted to they would probably not have taken place. He does not believe in a "quiet stage." It has been said that on the fifth or sixth day operations are apt to be unsuccessful, but that he holds it is because by that time abscess may have been formed. Precious time has been lost. To wait for a quiet stage may be waiting for the silence of death. There is, he admits, apt to be "Fool's Paradise Stage," for which he would not wait, as his time to operate is as soon as he suspects the appendix is inflamed. It is urged that if this course be pursued cases may be operated on in which no disease of the appendix is found. This he would not regard as a great calamity—a clean cut into the abdomen can do no harm, and in extreme doubt he would follow his surgical instinct to "look and see." An exploratory incision might well become a routine procedure. As regards other methods of treatment, Mr. Owen declared there is no place for general measures "until after the inflamed appendix is out."

As already stated, the speakers all supported Mr. Owen, though perhaps with less enthusiasm. Mr. Battle urged that early operation was not only life-saving, it shortened the period of illness, obviated the danger of hernia and to a degree the necessity of drainage. Still he did not advocate it indiscriminately in every case and at every stage. Mr. Childe considered any attempt to discriminate as putting back the clock, and he has had 700 cases. Mr. Grey Turner agreed and gave his experience of 681 operations with a total mortality of 5.13 per cent. Mr. George R. Turner, in his last 100 cases, had only one death. Mr. Renton said early operation was the only proper course in acute cases; it gave a mortality of 2 per cent. against 20 to 40 if delayed. Major Hull said if all could be operated on before pus was formed there would be no mortality. Mr. Clayton-Greene said high mortality was due to delay. Mr. Burgess confirmed this, as did Mr. Connell, of Sheffield, and the president, Sir Watson Cheyne, who said he always removed the appendix unless the patient was moribund.

Unusual interest was felt by many in a communication to the Pathological Section of the Royal by Mr. S. G. Shattock. It was the history of the case of the late Dr. W. Rivers Pollock, obstetric physician to Westminister Hospital, who bequeathed to the Royal College of Surgeons for dissection the parts concerned in his twenty-five years' struggle with an illness brought on by a race when he was twenty-four years of age, in perfect health and training. He won for Cambridge against Oxford the 120-yard hurdle race in 16 seconds. He said he held his breath all the time. At the end of the race he lay down on the grass and complained almost immediately of pain in the lumbar region. Put to bed, the superficial veins began in a few days to dilate and slowly progressed for six months, during which time he kept his bed. When he got up the distended veins were supported by specially made elastic parts reaching up to the thorax, and these he had to wear for the rest of his life—a period of twenty-five years, during which he had to bear his infirmity. This he did with quiet courage, the admiration of his friends. Of late years he suffered from attacks of phlebitis and thrombosis in the enlarged saphenous veins. Such attacks would be brought on by the pressure of crease in his clothing. He died on September 29, 1909.

The dissection showed the inferior cava, except the highest part, converted into a flat, impervious ribbon, most contracted and thinnest opposite and below the renal veins for 2½ inches distance. A portion cut away from the front of the vessel below the renals showed its lumen completely occluded. The common iliacs and portions of the external and internal preserved are also flattened and obliterated. The tributaries and trunks of the renals are pervious, but entrance into cava closed, as tested with probe. The upper divided end of inferior cava is pervious, but reduced in size. The hepatic veins were not occluded.

Mr. Shattock suggested that, as a consequence of the extreme distention of the inferior cava by holding the breath in the race, a localized rupture of the intima, or of this and the media, took place, followed by forcible extravasation of blood into the walls during the exertion; in short, that the lesion in its initial stage was the counterpart of a dissecting aneurysm of the aorta. Since the word aneurysm is confined to arterial dilatation while swelling of the veins is termed varix, Mr. Shattock thinks "dissecting varix" suitable for the initial stage of the condition supposed, though very soon the two lesions would lose their resemblance, as the internal pressure is maintained in the aorta but not in the cava.

At the Royal College of Physicians on Tuesday the first of the Goulstonian lectures was given by Dr. Arthur J. Jex-Blake on deaths from electricity, which he found on the increase. In this country there were twenty-five in 1901-3, twenty-five in 1908 and twenty-six in 1910. In Europe about two hundred occurred annually, and as many in America. The conditions of electrocution, he thought, did not throw much, if any, light on the causes of death in accidental electric shock. Death, he considered, was not due to interference with the cardiac nervous mechanism, and probably to the direct stimulus to the muscular tissue of the heart, applied suddenly with such force that the whole of the muscular fibers contracted simultaneously, each at its maximum force.

The upright posture—a characteristic of man—has been the subject of lecture by Prof. Keith at the Royal College of Surgeons. Anatomists and others have often drawn attention to the adaptations of the skeleton, trunk, and limbs required to maintain the upright position in rest and in motion. But functional adaptation is equally or even more important. Muscles are dependent on nerves and these on the circulation of the blood, in all of which differences can be traced between quadruped and biped. Prof. Keith's investigations convince him that the shape of the lungs and the mode of respiration are adapted to the postural mechanism, and that various disabilities and deformation are caused by failure on exhaustion of that mechanism. The supporting muscles are brought into action by their automatic nerves at the moment of taking the upright position. Hence the lecturer pointed out the importance of keeping them in health by exercise and other means, especially for persons leading sedentary lives. The subject is continued in another lecture this evening.

The Middlesex Hospital's annual report may be called encouraging. At the meeting yesterday Prince Alexander of Teck, chairman, stated the total income was higher than the previous year. The new entrance hall affords greater comfort to friends of patients on visiting days. It also adds considerably to the appearance of the building, and thanks are due to Mr. Edmund Davis, who made himself responsible for the cost. The chairman had also to announce a gift of £10,000 from a benefactor who wishes to remain anonymous for the present. This is to be devoted to a new pathological block and institute of hygiene. There was some decrease in the income of the cancer charity of this hospital, but it is hoped this fund will soon retrieve its success.

The annual meeting of Kings College Hospital was held yesterday—the final one in the old building, as it is hoped to open the new hospital in September. A sum of £150,000 is still required to allow the new buildings to be opened free of debt.

The Central Ophthalmic Hospital also held its annual meeting yesterday. The new buildings occupy an area of 10,000 square feet and have cost £20,000. It was stated that the whole had been spent on necessaries, ornamentation having been sacrificed to utility. There had been a decrease in subscriptions due, it is believed, to the insurance act. But a gift of £3,000 and a legacy of £2,000 had been received during the year.

Professor M. M. McHardy, of Kings College and Hospital, one of the most eminent ophthalmologists, died on the 8th inst., age sixty-one. You will remember his self-registering perimeter, invented in 1882, and still in constant use. His valuable contributions to ophthalmic literature must also be known to you. Though not robust, having sustained some damage to the heart in an early illness, he was full of life and delighted in work, laboring in his hospital appointments with a devotion that surprised those who knew how much he did. He was obliged to retire, however, two or three years ago, to the regret of all who knew him. He was greatly admired for his remarkable skill as an operator and esteemed for his genial personal qualities.

Major F. D. Browne, I.M.S., has died in India at the age of forty-two. He graduated at Durham in 1893, entering the Indian medical service (Madras) 1896, and reaching the rank of Major in 1908. He was medical officer of the 112th regiment.

The death is reported from New Zealand of Dr. G. A. Harrison, B.A. Cantab. 1888, who took the diplomas of the two Royal Colleges of London in 1893.

Surgeon-General Bidie, C.I.E., formerly professor of materia medica at Madras, Hon. Surgeon to Queen Victoria, King Edward and the present King, died on the 19th inst. During his Indian service he passed through the mutiny. He discovered the cure, or rather preventive, of the coffee disease which had prevailed in Southern India.

1. **Arthritis and Visceral Ptosis.**—H. W. Marshall states that enough observations have been made by surgeons to show that operations which overcome stasis, and those which sidetrack or completely remove from function certain defective portions of the gastrointestinal tract by anastomoses, resections, and colostomies, are followed in some instances by the subsidence of aggravated arthritic lesions. Visceral ptosis is so frequently an accompaniment of such defective conditions that by some it is considered the dominant feature of them. Equally well established also is the fact upon which certain internists lay emphasis, namely, that most marked degrees of visceral displacement may be present without symptoms of arthritic disease.

2. **Diverticulitis.**—J. Stanton concludes that this is not a rare disease. Recurrent attacks of left-sided abdominal pain, with tenderness and tumor formation, in the absence of any active urinary disturbance, are usually due to inflamed diverticula. As a focus of chronic irritation this condition may be a starting point of cancer of the sigmoid. Surgical removal affords the only perfect cure.

3. **Infection With the Dwarf Tapeworm.**—J. Gerber reports a case of this condition in a boy aged 17 years. Symptoms pointing towards the gastrointestinal tract were practically absent, the only important one being nausea. On the other hand, the chief disturbances were those referable to the nervous system, namely, severe headache, dizziness, and later convulsions and unconsciousness. The diagnosis is usually difficult, as there are ordinarily no symptoms pointing to an intestinal parasite. Sometimes there are gastrointestinal symptoms: diarrhea alternating with constipation, colicky abdominal pains, vomiting, and severe nausea. Frequently nervous symptoms greatly outweigh

the others. These are usually very severe, and may consist of headaches, disturbances of vision, dizziness, convulsions, spasms, fainting-fits, and pains in various regions. Often a very severe secondary anemia develops. The diagnosis can be made only by finding in the stools the characteristic ova, or more properly speaking, "onchospheres," as they contain an embryo. These have a thick double capsule, within which is found the embryo containing six hooklets. At either pole is a so-called "mamilate" tip, from which several filamentous appendages go off into the surrounding protoplasm. It is the possession of these filaments that distinguishes the *Hymenalepis nana,* or *Tenia nana* as it is more commonly called, from other members of the same genus. The dwarf tapeworms themselves are too small to be noticed in the stool with the naked eye, unless present in very large numbers, as after treatment. In the adult stage they measure only from 5 to 45 mm. in length, although they contain 100 to 200 segments. This is the smallest tapeworm known for man. It is usually a parasite of children, about 70 per cent. of the reported cases being in children under the age of 15.

1. **Infant Feeding.**—J. L. Morse states that the average well baby thrives better during the early months on foods in which the natural relation of the fat, sugar and proteid are retained. Many infants are given too much fat in their food. Under normal conditions lactose is preferable to maltose in the feeding of infants and there is no indication for the use of saccharose in the place of these sugars. The reasons for this belief are that lactose undergoes lactic acid fermentation, which is the normal one in the infant's intestine, more readily than the other sugars and that it is more suitable for the development and maintenance of the normal infantile intestinal flora than the other sugars. It favors especially the development of *Bacillus bifidus,* which is normally the predominant organism in the large intestine. There is a kind of intestinal indigestion in infants which is due to the fermentation of milk sugar and the dextrin-maltose mixtures are most useful in the treatment of this condition. In the acute diarrheas due to bacterial infection the sugar given should be determined by the nature of the infection. In the type caused by the gas bacillus and other organisms of its class large amounts of any sort of sugar are contraindicated, maltose being more harmful than lactose because it undergoes butyric acid fermentation more readily. This type of diarrhea yields most rapidly to treatment with lactic acid bacilli. The average well infant thrives better during the early months on mixtures containing relatively high percentages of fat and sugar and relatively low percentage of proteins. There is a tendency to give higher percentages of proteins, on the average, than was the custom some years ago. However, if the proteins are increased too much beyond the protein needs, an unnecessary strain is thrown on the protein metabolism and on the organs of excretion. There is a protein indigestion in the same way that there is a fat and a sugar indigestion. Protein indigestion is more often overlooked than the others because it is harder to recognize, and when its symptoms are better known, it will be found to occur far more frequently than many at present suppose.

2. **Urethral Lithiasis.**—V. C. Pedersen notes that the symptoms of lithiasis of the anterior urethra with impaction in young children are objective only, and consist in outcries of pain and straining to pass urine which is voided, if at all, only in drops. In adults, however, the cases fall into two groups: First, patients who give little history until the urethral obstruction suddenly appears; and, second, patients who present a logical and consecutive story of varying degrees and forms, separated by widely uncertain lapses of time, brief in some, longer in other individuals, of renal disorder, with pain, pus, blood, ureteral colic during the migration of the stone into the bladder, vesical irritation from its presence in the bladder, and finally the urethral obstruction, absolute or relative in degree. Sometimes such patients have noticed the passage of urinary sand and stones, too small to cause obstruction. The immediate results of the obstruction provide the next set of symptoms alike in character, but more severe in children than in adults, namely, shock, anuria, retention of urine, distended and tender bladder, rupture of the urethra, and extravasation of urine, especially in children. These are variously related with absolute obstruction. Slight or partial obstruction may give few symptoms so that sometimes stones may be retained with little inconvenience for years.

4. **Indurative Headaches.**—A. Maverick finds that the diagnosis of indurative headache is easy when its frequency is kept in mind. It is possible to mistake the natural roughness of the occipital bone for indurations. Periodical attacks of indurative headache are often mistaken for migraine. In migraine, however, there are no sensitive muscular nodules, and between attacks the scalp is not apt to be sensitive to touch; furthermore, the pain when severe does not radiate down the back out to the shoulders, and painful stiffness of the neck does not usher in an attack. The pain of indurative headache is not preceded by a sensitive aura, nor terminated by vomiting. Migraine almost invariably begins in early youth, but indurative headache usually arises in adults. The commonness of unilateral headache and of ocular symptoms in migraine is also to be remembered. The final test is the treatment; the massage which cures most cases of indurative headache has no such influence on true migraine, and the cases of migraine that are reported as cured by massage are usually all cases of indurative headache. The two conditions may be associated, and muscular indurations may attack victims of migraine as well as others. These indurations (*Muskelschwielen*), as the name indicates, are composed of fibrous tissue thickenings; in early stages they are edematous and feel soft or elastic, but as the fibrous tissue contracts they become hard and dense. They arise in the muscle sheath and its proliferations into the muscle substance, also in the subcutaneous connective tissue, the condition being really more of a fibrositis than a myositis, strictly speaking. The underlying cause is apparently some nutritive change in the muscles involved, possibly an insufficient blood supply caused by the lack of exercise, or what some writers speak of as a rust of the tissues or premature senility of the muscles. The pressure caused by the contracting fibrous tissue on entangled nerves is apparently responsible for the pain.

7. **Bloodletting.**—F. H. Garrison quotes Haviland and Hall, who in a recent study of the subject, sum up the modern indications for bloodletting as follows: (1) Cases of an apoplectic nature, especially when associated with coma and cyanosis. (2) Cases of high tension and granular kidney in connection with arteriosclerosis. (3) Cases of convulsions in the status epilepticus. (4) Cases of uremia. (5) Cases of sunstroke with asphyxia. (6) Cases of polycythemia. (7) In hemoptysis, if there be engorgement of the right ventricle of the heart. (8) In aneurysm for relief of pain. (9) In cases of dilatation of the right ventricle of the heart from whatever cause aris-

ing. (10) In cases of pneumonia, for relief of pain and dilatation of the right ventricle.

10. **Urethritis and the Micrococcus Catarrhalis.**—E. H. Siter points out that a great many of the so-called cases of chronic urethritis are in reality infections caused by the *Micrococcus catarrhalis*, and if this is not recognized, the patient is treated vigorously, either with sounds or local applications, and the case drags on indefinitely. If many of one's so-called chronic prostatic and chronic urethritis patients were subjected to a careful bacteriological examination the absence of gonococcus could be determined, and if one went a step further and took a culture the *Micrococcus catarrhalis* would be revealed.

2. **Surgical Treatment of Chronic Dyspepsia.**—W. H. Wathen classifies the causes of chronic dyspepsia as follows: (1) In 90 per cent. of the cases of chronic dyspepsia there is no trouble in the stomach. In about 30 per cent. the stomach trouble is caused by cardiac and kidney insufficiency, tuberculosis, arteriosclerosis, tabes dorsalis, etc. Another 30 per cent. of cases are caused by congenital or acquired defects in the viscera of the abdominal and pelvic cavities, plus gastrointestinal neuroses—gastroptosis, enteroptosis, atonic dilatation of the stomach, etc. Dyspepsia is often cured by the removal of gallstones or of the appendix. There is but one treatment that can cure inveterate dyspepsia due to calloused gastric or duodenal ulcer, and that is surgery. Temporary cures may be obtained, but the symptoms will return.

3. **Tuberculin Treatment of Tuberculosis.**—A. P. Francine and H. J. Hartz report the favorable results attending the use of Dixon's tuberculin in the treatment of advanced cases of tuberculosis, which all belong to the fibroid type, moderately or far advanced with little or no fever. The patients had developed a fair resistance to the disease but yet showed a very gradual deterioration in weight and strength in spite of all that had been done. The tuberculin was put up, not unlike the diphtheria antitoxin, in ten different dilutions, the weakest representing 0.001 and the strongest 0.09 mg., and was injected into the interscapular tissues of the back, in small doses at the beginning, which were gradually increased as tolerance was established. Care was taken to avoid even slight reactions. The authors report eleven cases in detail. In all the deterioration was checked. The patients were able to resume their occupations and remain at regular work during or after the injection, which seemed to be the sole factor in the improvement. The patient with glandular tuberculosis was apparently cured. Tubercle bacilli disappeared in the sputum in several of the cases during the treatment, but were still found in the majority at the close of the treatment. The local condition of the lungs showed a distinct improvement, as evidenced by the disappearance of râles. The authors conclude that in advanced tuberculosis, when there is fair resistance and little or no fever, tuberculin is unqualifiedly a therapeutic measure, or at least proved to be such in this series. The reactions with Dixon's tuberculin (tubercle bacilli extract) were uniformly mild and without unfavorable influence on the treatment. The authors believe that, for general use at least, particularly in ambulatory cases, it is better to select a mild and little toxic preparation, and Dixon's they consider a safe and effective tuberculin of this type.

4. **Local Application of Horse Serum in Hemorrhage.**—C. G. Levison cites two cases of persistent hemorrhage, one from the bladder after cauterization and the other from the exposed gall-bladder after an exploratory operation for carcinoma, both of which were relieved at once by local applications of horse-serum instead of by the usual hypodermic injection or transfusion. In each case a flask of horse-serum was poured into the open bleeding surfaces, causing prompt and permanent cessation of the hemorrhage.

6. **Fecal Impaction in the Ileum.**—R. H. Harris notes that cecostomy may be complicated (a) by contraction of the opening, requiring dilatation from time to time; (b) by fecal impaction, necessitating irrigation through the artificial anus, and (c) by prolapse of te cecum through the cecostomy fistula. Fecal impaction in the ileum in the case reported by the author was due principally to the ingestion of fruit seeds and imperfectly masticated vegetables, such a trong bean, which became impacted at the ileocecal orifice. Mere fecal accumulation does not cause urgent symptoms as long as the intestinal gases have opportunity to exit. The distention may produce displacement of the liver and stomach without marked interference with their functions. The urine became dark red from the elimination of bile pigments and hematin reduced to urobilin in the intestine, and the urine contained a few hyaline casts but no albumin. Röntgen-ray examination of the digestive tract after bismuth meals and bismuth enemas was valuable in enabling one to confirm the extent of the changes which resulted from the impaction and estimate the exact location of the tumor. Treatment to be effective must be persevering and should be conducted with full knowledge of the probable existence of stercoral ulceration in a greatly distended intestine and of the possibility of separating the bowel from the colostomy opening by any undue violence. Prolapse of the cecum through the artificial anus may prove fatal unless skilful surgical attention is promptly available.

10. **Intestinal Obstruction.**—A. McGlannan presents a clinical study of 181 cases of intestinal obstruction, undertaken to find the clinical picture that will enable one to recognize obstruction in its early curable stage and to determine what extent of operation should be performed when the condition is complicated by toxemia and gangrene. The reports include twenty-seven varieties of obstruction, exclusive of strangulated hernia, taken from the records of the Johns Hopkins and St. Agnes' hospitals, Baltimore. The patients were operated on by fifteen surgeons during a period of twenty years. The early characteristic symptoms are pain, constipation, diarrhea and vomiting. The association of pain and constipation at the onset occurred in 30 per cent. of the cases, though vomiting may be an initial symptom. The secondary symptoms are due to the efforts of the intestine to force its contents beyond the point of closure and the effect of these efforts on the size and shape of the bowel and the effects on the blood-vessels involved in the obstruction. In the third or last stage there occur toxemia gangrene, peritonitis and alterations of kidney function. Thirty-four patients were treated in the first stage, twelve by enemas and purgatives and thirty-two by operation—resection, simple enterostomy, enterostomy with short circuiting, division of bands, and reduction of hernia, intussusception, and

volvulus. All recovered. Sixty-five persons were operated on in the second stage. Ten died from the operation and eleven from a second operation or some complication occurring more than a week afterward. In both first and second stages, therefore, operative relief of the obstruction seems the best treatment. Eighty-two patients were operated on in the third stage, with fifty-two deaths. Five of those who survived the operation died as a result of complications. In the third stage enterostomy should be done either alone or in connection with other measures. It is necessary when toxemic symptoms appear to remove the toxic accumulations above the obstruction. Whether or not one should do more depends on the general or special condition of the patient.

8. Functional Aphonia: A Method of Curative and Preventative Treatment. C. Macmahon.

1. **Exophthalmic Goiter.**—J. Berry states that the most striking naked-eye feature of the thyroid gland in cases of this condition is the very marked diminution in the amount of colloid, often amounting to complete absence. The gland, instead of presenting the vesicular appearance so characteristic of the normal gland, or of the ordinary parenchymatous goiter, presents a solid, almost homogeneous, appearance. Instead of looking like a sponge or a honeycomb, as does the socalled parenchymatous or colloid goiter, it resembles a solid organ like the salivary gland or the pancreas. There is another group to which the name of secondary Graves' disease may be given. These are cases in which the symptoms and pathological appearances of the disease are engrafted upon a previously existing simple goiter, either a cyst or an adenoma, a parenchymatous or an adenoparenchymatous goiter. There is another type which is quite common clinically, but which in the author's opinion, should not be classed as Graves' disease nor even as hyperthyroidism. These are cases of ordinary goiter, generally a deeply seated cyst or adenoma, with dyspnœa and tachycardia, and often, too, some degree of tremor and even emaciation. They do not present the characteristic morbid appearances of hyperthyroidism. But if left alone they show no tendency to develop exophthalmos, they do not run the ordinary course of Graves' disease, and they are not attended by the grave risks of that disease. With regard to the exophthalmos, which is so striking and remarkable a feature of Graves' disease, there can be little or no doubt that it is due solely to local accumulation of fat within the orbit. A condition of heart, to which the name of "kropfherz" (goiter heart) was given years ago by continental surgeons, is in its severe and later stages a serious cause of anxiety to the operating surgeon, and the author has had to deal with only too many of these cases. The condition is due to long-continued mechanical pressure upon the trachea and veins at the root of the neck. There is, however, another kind of goiter heart in which the rapidity and irregularity of the heart are probably due to chronic poisoning by thyroid secretion. Such is the heart of Graves' disease.

3. **Live Attenuated Vaccines in Typhoid and Paratyphoid Fevers.**—A. Castellani records the results following the use of live attenuated vaccine prepared according to the method introduced by him in 1904. In preparing the vaccine the strain used should be non-virulent but rich in antigen, as found out by animal experiments. Such vaccine in the lower animals, and probably in man too, gives rise to a higher degree of immunization than obtainable with dead vaccines. In man, however, the immunization obtained by two inoculations of this vaccine or any of the dead vaccines is never complete; it is only partial. Cholera and dysentery attenuated live vaccines can be obtained by using a somewhat similar method as that for preparing the typhoid vaccine; but for the dysentery vaccine peptonewater cultures and not broth cultures should be used, as these give rise to an extremely painful infiltration at the site of inoculation. The author refers to the sensitized live vaccine prepared in 1911 by Metchnikoff and Besredka, but their results seem to be extremely good, as shown by Alcock. The experimental work of these observers on live vaccines is of great importance, having demonstrated that chimpanzees can be rendered immune to typhoid fever only by the inoculation of living vaccines, either sensitized or non-sensitized. Various mixed vaccines can be prepared, either dead or live attenuated vaccines. The inoculation of such mixed vaccines is harmless and apparently in the lower animals they induce a degree of multiple immunization, the blood developing protective substances for each of the germs inoculated. In countries in which paratyphoid A and B are endemic besides typhoid fever, a mixed vaccine of typhoid, paratyphoid A, and paratyphoid B should be used. If a live mixed vaccine should be objected to, a dead mixed vaccine can be used with satisfactory results. The inoculation of such vaccines as shown is harmless, and it is probable that they give a certain degree of immunization for all three infections.

4. **Miners' Nystagmus and Working Capacity.**—S. Riseley states that when a man claims to be and is admitted to be incapacitated by nystagmus, after a reasonable period during which he has been under constant observation, if his condition warrants his being employed, he should eventually resume work under ground, but as a commencement occupation above ground should be provided. For there is no doubt that a man with bad nystagmus can work and do good work, and is no worse for doing it.

1. **Death by Electric Currents.**—A. J. Jex-Blake notes that when one comes to look into a number of both fatal and non-fatal instances of accidental shock by industrial electric currents, it becomes apparent that the part of the body through which the current flows is extremely important in determining the result of the shock. Practically speaking, there is not the smallest danger of sudden death if the current enters one foot or leg and leaves it by the other or by the lower part of the trunk, however high the voltage and however great the current thus forced through the lower part of the body and the legs. But there is a danger, even with electric currents of as low a voltage as 65 volts, when the current travels through the thorax, and so has the chance to pass through the substance of the heart. The degree of danger here depends upon two factors—first, the resistance presented to the flow of electricity by the skin at the points at which the current enters and leaves the body, and, secondly, upon the voltage of the current. The resistance of the

skin varies very widely in any given case, being high when the skin is greasy or dry, or when the area of contact with the electric conductor is small, and relatively low when the skin is wet or the area over which it comes into contact with the conductor is great. To give a single example illustrating the author's meaning, one may handle a bare wire carrying, say, an electric lighting current at a pressure of several hundred volts with complete impunity, so long as the hands by which the current enters or the feet or boots by which it leaves the body are dry, because in these circumstances the amount of current flowing through the body is too small to be dangerous. But if the hands and feet are damp or wet, the electrical resistance of the skin at the points of entry and exit of the current may be so much lowered that a relatively strong current will flow from the hands through the body to the feet; and if the proportion of this current that passes through the heart is strong enough to paralyze it, then sudden death will occur.

**5. Application of Fungi as Styptics.**—E. Knight states that several species of fungus were largely used in former times as applications for arresting hemorrhage, both by surgeons and the common people. One of these is agaric. But the giant puffball, *Lycoperdon giganteum*, has had a far more lasting reputation as a styptic. The pulp consisting of powdery spores has been used by the peasantry for centuries to stop hemorrhages. The giant puffball was used in surgery as early as 1560. Within recent times it has been recommended as a useful styptic when applied locally in cases of hemorrhoids, in epistaxis, in uterine hemorrhage, and in troublesome bleeding after the extracting of a tooth. Heating the puffball in an oven to render the dressing aseptic does not appear to impair its hemostatic properties.

**6. Gastroenterostomy for Peptic Ulcer.**—A. W. Bourne discusses the after-history of cases of peptic ulcer in which gastroenterostomy has been performed. The results of treatment by gastroenterostomy are generally either excellent cures or complete failures. The immediate mortality of 92 cases is 7.6 per cent., but of the last 53 cases it is 0. The general results are: 43 per cent. excellent; 38 per cent. bad. Prognosis is much better when the patient is over 40. According to sex, 69 per cent. of males are cured; 28 per cent. of females are not improved. The duration of symptoms is of no assistance in forecasting the result of operation. The length of time elapsing between the meal and the onset of the pain is of great importance; the longer it is the better the outlook. Duodenal ulcers yield very much better results than gastric ulcers; the gastric give 38 per cent. of cures, duodenal 70 per cent. of cures. Cases of pyloric stenosis yield the best results. The degree of hyperchlorhydria is of importance, cases showing a total acidity of over 0.2 per cent. reacting well, cases with a normal acidity doing badly. The improvement effected by the operation is probably due to the relief dilatation, pyloric spasm, and hyperacidity by the drainage of the stomach. Failures may follow the closing of the anastomosis. The position of the anastomotic opening on the posterior wall of the stomach may be of great importance. Failures may be due to recurrence, or failure to heal of the original ulcer, or to the formation of jejunal ulcer. Apparent relapses are due to adhesions causing pain, vomiting, etc, or to carcinomatous degeneration. Cases in which an ulcer is not found at operation do badly.

### Berliner klinische Wochenschrift.

*February* 24, 1913.

**Pancreas, Liver and Carbohydrate Metabolism.**—Wohlgemuth, after commenting on the work in this field by von Mering and Minkowski and other investigators, introduces new data from his own studies, as follows: The diastase of the pancreas and blood is active in carbohydrate metabolism. The pancreatic juice is absorbed into the blood in enormous amounts after ligation of the pancreatic duct, the diastase being recognizable therein in greatly increased proportion. Experiments with dog's blood show that the percentage of diastase increases twenty to thirty fold after the juice has been poured into the intestine. Such an augmentation cannot be without influence on the carbohydrate and glycogen metabolism. In an auxiliary series of experiments animals were fed abundantly on glucose, and in certain of them the pancreatic duct was ligated. In about three days the animals were killed and the livers investigated for glycogen. The amount of the latter in the livers of animals with ducts not ligated was tenfold that of their fellows, a condition foretold by the weight and texture of this organ. In several of the operated animals there was barely a trace of glycogen left. But the pictures changes if the time set for death is prolonged to a week or ten days, for in that case the intact animal appears nearly to have lost its glycogen values. Furthermore, Bernard's sugar puncture does not cause any essential variation. In other words, ligation greatly accelerates the disappearance of the stored-up glycogen. Another discovery was as follows: If the duct was tied before the glucose cramming was begun the glucose at once appeared in large quantities in the blood, or, in other words, a severe sugar intolerance developed. Numerous other finds were obtained, and the author concludes as follows: A saturation of blood with pancreatic diastase causes a revolution in carbohydrate metabolism. Glycogen may nearly vanish from the liver, so great is the diminution of its content. The tolerance for sugar is disturbed, the percentage of blood sugar notably increased—the blood sugar and blood diastase fluctuating together. The increase in the former has no absolute connection with increased combustion of sugar, *i.e.* is not parallel with it, but the latter is disturbed. Increase in sugar content of blood never leads to glycosuria. The facts still remain, however, that under normal conditions an increase of blood sugar should either be oxidized or escape by the urine. That neither result occurs in the author's animals appears to be due to the fact that something in the absorbed pancreatic juice interferes with the renal functions.

**Corneal Anesthesia from Quinine Derivatives.**—Morgenroth and Ginsberg have produced with a series of quinine synthetics an anesthetic action on the cornea which is far more intenstive than that of cocaine. This discovery, made some months ago, appeared at first to be invalidated for practical purposes by the concomitant initiating action sometimes in evidence, which was of a kind even to cause blindness. Further study of the group has shown not only an enormous anesthetic action—for isoamylhydrocuprein is from 20 to 25 times as active as cocaine—but positive therapeutic properties. The isopropyl combination produces an anesthesia lasting several days. While some members of the group are non-irritating to the rabbit's eye, others—and these the most powerfully anesthetic—may cause chemosis and opacity of the cornea. The future promises a synthetic in this series which by its prolonged anesthesia may be of special value in treating painful affections. In addition, these synthetics are known to antagonize bacteria—notably the pneumococcus—and thus fill two indications at once.

### Münchener medizinische Wochenschrift.

*February* 25, 1913.

**Against the Endemic or Drinking Water Etiology of Goiter and Cretinism.**—Kutschera cites the 171 authors mentioned by Scholz who hold fast to a belief in the water

borne origin of these two affections. The impetus to the opposing or epidemiologic theory proceeds largely from the teachings of Wagner von Jauregg. The theory of simple primary hypothyroidism has naturally no adherents, although the malady undoubtedly strikes the subject largely through incapacitation of the thyroid body. The author's chief contention is that goiter and cretinism occur *en masse* under circumstances which quite exculpate the drinking water of the community; in other words, they occur in populous territories, in which a water borne disease would attack a greater percentage of individuals. If we plot off two regions, one based on water supply only and the other on habitations, we find invariably that incidence goes by residence and not by common drinking water supply. Goiters and cretinoid states may be established in animals without drinking water standards. To oppose successfully the water borne theory, we can only urge that the incidence is best accounted for by personal transmission through some hypothetical intermediary. The author, having no direct evidence of the latter, concludes from analogy that the two maladies are spread by minute hosts, such as are in full evidence in certain tropical diseases. Very recently evidence has been offered in tropical countries that a cretinoid condition may be set up by the sting of a bug which acts as host for a trypanosome. One of these affections—the so-called Chagaz disease—is no doubt a powerful auxiliary for those who seek to demolish the endemic theory of goiter.

**Occurrence of Tubercle Bacilli in the Circulating Blood.**—The great interest of this subject is shown by the simultaneous appearance of papers by Querner of the Hamburg-Eppendorf Hospital and Rosenberg of Hagen. While most of the recently published articles on the Continent do not allude to the impetus given to this research by American authors—notably Rosenberger—the article by Querner does full justice to the same. Both authors appear to believe fully that our actual information along these lines has become much confused and that no orientation, to say nothing of progress, is possible until we can establish better standards of identity.

**Treatment of Wounds with Sugar.**—Magnus refers to the great antiquity of this usage—even Galen treated fetid wounds with honey. The same idea obtains in amateur domestic practice to-day. On account of the frequent outcropping of this idea in the history of medicine—"school and popular"—the author has investigated the subject anew, being incited in part thereto because of the peculiar reactions of culture media which contain sugar upon bacteria, and also because of the recent use of sugar in intraperitoneal surgery and in other associations in which harmless antiseptics are indicated. He concludes that sugar as an antiseptic in wound treatment requires further attention. Sugar has a disinfectant and antiputrefactive action, dissolves fibrin, and incites secretory activity through violent osmotic action. In other words, it is a harmless, cheap, and apparently sterile medicament for routine wound treatment.

## Deutsche medizinische Wochenschrift.

*February 20, 1913.*

**Detoxication of Tuberculous Foci by Röntgen Radiation.**—Iselin sums up his personal experience as follows along with the results of much collateral effort: Regular determination of weight has shown: 1. That during the radiation period there is a gain in from 70 to 80 per cent. of two pounds or more. 2. As a rule there is a further gain in weight with each sitting, and with the increase in weight comes a parallel shrinkage in the focus, the loss of weight being due to toxin formation in the focus. The increase in weight which follows the radiation is to be conceived as due to a partial detoxication of the focus, and probably consists in improved water retention. The shrinkage in local lesions is doubtless the result of improved circulatory conditions. Thus is explained the initial improvement, but the permanent gain is to be explained only by actual healing of the focus. In surgical tuberculosis of mild type repeated weak radiations may answer the purpose, while in severe types there must be energetic deep radiation, not with the idea of a physiological cure, but a destruction and cicatricial retraction or encapsulation.

**Rationale of Bromine Therapy of Epilepsy.**—Von Wyss mentions the increased bromine retention which always results from prolonged bromide ingestion, with corresponding loss of chlorides. Organic bromine compositions in contrast with the alkaline bromides show less retention, certain organs containing no bromine at all. The expulsion of chlorine from the body during bromine administration may be considerable. If we give an animal large doses of bromides and small quantities of salt we see develop ataxia, and severe psychic alterations. If in such cases we give salts freely the symptoms rapidly yield. This is one of the most interesting phenomena in therapeutics. The introduction of salt drives out the bromine ions and restores to the body its content of chlorine ions. On rational grounds therefore salt starvation is contraindicated. Whenever bromides are given over long periods they must not be allowed to drive out all the chlorine; and when we go to the extreme of cutting salt out of the diet we favor the very worst expression of bromism. Rather we should never give bromides without the simultaneous exhibition of small doses of sodium chloride. But to secure the needed economy in bromide a salt-poor diet is not contraindicated. It is well to keep the patient on the smallest necessary dose in order that the latter may be increased in emergencies. The author admits that his views have to be submitted to the exigencies of actual practice, and hopes that this result will be forthcoming. One important point is that salt-poor diet is not always expedient and that there is a class of epileptics in which the patients may be allowed salt to taste.

---

**Action of Atropine and Pilocarpine on the Urinary Secretion.**—D. Cow has found that the chief action of atropine on the excretion of urine is one on the plain musculature of the ureters. Pilocarpine affects the output of urine both indirectly through loss of fluid from other glands and also, and probably to a greater extent, by its action on the musculature of the ureters.—*Proceedings of the Royal Society of Medicine.*

**Edema Neonatorum.**—E. G. Graham Little notes that the distinction between edema and sclerema is carefully made and insisted upon by Radcliffe-Crocker, although often confused by other authors. The variety in a patient reported by the author was difficult to class, for it was essentially an edema, but there was no lividity, and the skin was waxy-white and smooth. The process, however, was transient in duration, and when the swelling was over the skin seemed but little altered, slight desquamation being present. The patient was a female, aged six weeks. The edematous change had been noticed at first in the feet and legs, then in the forearms and hands, but had not become generalized. The child when shown had a white and solid edema of both the forearms, which ceased abruptly at the elbow, where there was a definite ridge separating the healthy tissue from the diseased. The legs had by now regained their usual size and aspect. The child, seen four days later, showed no signs of edema of the forearm or hands, and seemed to be otherwise in fairly good health. There was no reason to suspect syphilis, and she had not had diarrhea. Previous cases seen by the author had invariably ended fatally, but the prognosis in this case seemed favorable.—*Proceedings of the Royal Society of Medicine.*

## Insurance Medicine.

**Prognostic Significance of Albumin and Casts.**—Dr. C. N. M'Cloud says that a most puzzling as well as interesting problem in insurance is the prognostic significance of urinary albumin and casts. A study of the literature on the subject is very confusing for authorities differ a great deal in their conclusions in the matter. The presence of albumin in the urine has been regarded as a sign of kidney disease by layman and physician since the time of Bright, in spite of much evidence to the contrary, for albumin may be absent in kidney disease and be present without it. The following may be included among "innocent" albuminurias: (1) Paroxysmal or cyclic albuminuria; (2) Dietetic albuminuria; (3) Albuminuria after exertion or cold; (4) Simple persistent albuminuria; (5) Postural or orthostatic albuminuria; (6) Climatic changes causing albuminuria; (7) Alimentary albuminuria (Crofton).

1. Paroxysmal albuminuria is marked by a large quantity of urine, few or no casts, and a regular rise or fall in the amount of albumin during the twenty-four hours. Albumin begins to appear soon after rising, increases during the day, falls on going to bed, and disappears at night to reappear the next morning. Young males are most liable to this condition, and are usually anemic, suffer from headaches, neuralgic pains, languor, etc. The differential diagnosis between this form of albuminuria and real nephritis may be very difficult, and doubtful for months.

2. Dietetic albuminuria occurs in children and adults, the amount of albumin being small with few or no casts. It may follow the ingestion of certain foods, eggs or cheese, for instance. If this albuminuria is temporary, the prognosis is good; if it persists, the patient is to be regarded with suspicion.

3. Albumin may appear after severe and prolonged exertion, such as marching, boxing, wrestling, etc. Usually the amount of albumin is considerable and numerous casts are present. Congestion of the kidney is the usual explanation. Repetition of such congestion might be followed by the development of true nephritis.

4. Simple persistent albuminuria means the presence of small quantities of albumin for years, usually not at all hours of the day. Few hyaline casts may be present; both they and the albumin may disappear after rest. One should feel anxious about such persons, as sooner or later they may develop chronic interstitial nephritis or endarteritis.

5. Many writers agree that there is no real postural albuminuria but that this is simply a characteristic of certain albuminurias of organic or functional origin.

6. Sudden changes of temperature have some effect upon the activity of the kidneys and albumin may appear during the extreme temperatures.

7. Alimentary albuminuria. Dr. Crofton has shown that whenever undigested albuminous food remains for a long time in contact with the gastrointestinal mucosa a portion of the native albumin may be absorbed into the circulation and promptly excreted as a foreign proteid. This may occur in motor insufficiency of the stomach, in certain intestinal indigestions, in hepatic insufficiency of marked degree, in rectal feeding with certain proteid foods, after ingestion of large amount of albuminous foods, etc.

Prognosis in all such types of albuminuria is very difficult because but few patients have been followed for years. Barringer has followed 396 men who showed albumin at the time of insurance and found ten years later that of the "albumin group" four died of the "albumin and hyaline casts group" thirteen died, of the "albumin and granular casts group" eight died. Altogether there were twenty-five deaths as contrasted to sixteen that could be expected, if the men were normal and sound in every particular. Barringer also showed that the incidence of tuberculosis among people with albuminuria seems to be very much higher than among the rest of the population. The albuminuria must therefore be looked upon as a sign of lowered resistance, at least, if not a very early accompaniment of an existing tuberculous infection. In determining the prognostic significance of albumin in an applicant, other features must be carefully examined, especially the condition of the heart (enlargement) and of the bloodvessels (sclerosis), and the blood pressure. The amount of urine passed in the twenty-four hours and the specific gravity should be ascertained. These points may help one to exclude cases of chronic nephritis but the significance of albuminuria will not be cleared up until more statistical and clinical knowledge is at hand. Collective investigations of several insurance companies will probably throw much light upon the matter. In conclusion it may be stated that all applicants with albuminuria should be regarded as substandard risks and an increased premium should be demanded from them.—Proceedings of the Second Annual Meeting of the Medical Section of the American Life Convention.

**Malingering in Accident and Disease.**—Sir John Callie states that the cost of insuring against accidents to industrial workers is now far in excess of the actuarial estimates upon which compensation acts are based, and the study of the statistics in relation to non-fatal accidents shows an increase in the number of these accidents which cannot be accounted for even by the speeding up of machinery and the conditions of modern labor. Malingering and dishonesty have an influence in raising the figures to their present abnormal height. The detection of malingering is not always so much a question of scientific knowledge as of the personal equation of the examining medical officer. For a number of years the author has examined annually about 2,000 sick and injured work-people with reference to their ability to return to work, and of these he has certified 25 per cent. as fit to work. The majority of these were not typical malingerers, but they would, nevertheless, from various causes, have unduly prolonged their illnesses. The principal means by which to check malingering are stated briefly as follows: (1) A system of organized lay-inspection; (2) repeated, periodical, independent medical supervision; (3) complete independence of the medical attendant, and (4) some system of registration which shall make apparent the full amount of sick pay and other benefit, if any, of which the patient is in receipt.—*The Lancet*, February 1. 1913.

**Workingmen's Insurance.**—A bill has been introduced into the New York Senate providing for insurance against industrial accidents. The bill permits employers to select any one of four different forms of insurance—self-insurance under restrictions, mutual insurance, insurance through a State fund, or insurance in an authorized stock company.

# Book Reviews.

Surgery and Diseases of the Mouth and Jaws. A Practical Treatise on the Surgery and Diseases of the Mouth and Allied Structures. By Vilpray Papin Blair, A.M., M.D., Professor of Oral Surgery in the Washington University Dental School, and Associate in Surgery in the Washington University Medical School. With 384 Illustrations. Price, $5. St. Louis: C. V. Mosby Company, 1912.

The study of the mouth and of its diseases belongs not only to the province of the surgeon and dentist, but also to that of the general practitioner. Many constitutional diseases are revealed by characteristic changes in the mouth, and at the same time pathological conditions in this cavity give rise to constitutional derangements. Parallel with the recognition of these facts, recent years have beheld a phenomenal development in the specialized surgery of the jaws and teeth. The present volume in its thorough presentation of this entire subject adequately mirrors the rapid progress that has been made in this branch of medicine and surgery. The importance to the dental student of a knowledge of the fundamental principles of surgery is emphasized in the chapters devoted to the inflammations, infections, asepsis, hemorrhage, shock, etc. The subject of fractures of the jaws is presented in great detail. The same is true of the subject of congenital clefts of the palate and lips. Among the other topics that are discussed in satisfying detail may be mentioned deformities and malrelations of the jaws; diseases of the temperomandibular joint; infections of the teeth, peridental tissues, and jawbones; septic infections of the floor of the mouth and neck; diseases of the maxillary sinus; diseases and tumor of the lips, floor of the mouth, and tongue; and diseases of the pharynx. There are separate chapters on the ligation and temporary constriction of the arteries, on motor derangement, on tic douloureux, and sphenopalatine neuralgia, on local anesthesia, and on general anesthesia. The illustrations which are numerous and clear add considerably to the value of this volume, which may be recommended as one of the best of its kind that have appeared within recent years.

Mind and Its Disorders. A Text-Book for Students and Practitioners. By W. H. B. Stoddart, M.D., F.R.C.P., Resident Physician and Medical Superintendent of Bethlehem Royal Hospital; Lecturer on Mental Diseases to the Westminster Hospital, the Royal Free Hospital, and the London School of Clinical Medicine; late Educational Secretary of the Medico-Psychological Association of Great Britain and Ireland. Second Edition. With Illustrations. Price, $4 net. Philadelphia: P. Blakiston's Son & Co., 1912.

In the first edition of this work, which appeared about three years ago, the author stated in his preface that his object was to provide the student and practitioner with a succinct account of existing knowledge of mental diseases. This he seemed to accomplish fairly well and the book met with a ready sale. The endeavor was made "to induce the reader to think neurologically of mental processes, normal and morbid." In the plan of the book, normal psychology is first discussed; then the psychology of the insane; and lastly mental diseases. The classification employed is that of Kraepelin, slightly modified. There were 42 chapters in the first edition. Nearly all of these have been revised to bring the subject-matter up to date, and two chapters being on psychoanalysis have also been added for the same purpose. The book is a good step in the right direction and may be recommended as a helpful guide to both the student and the practitioner, in the study of the various disorders of mind.

Internal Secretion and the Ductless Glands. By Swale Vincent, M.D. (Lond.), D.Sc. (Edin.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), F.R.S.S. (Edin.), and Canada), Professor of Physiology in the University of Manitoba, Winnipeg, Canada, formerly Assistant Professor of Physiology in University College, London. With a preface by Professor E. A. Schäfer, F.R.S. Illustrated. Price $3.50. New York: Longmans, Green & Co., 1912.

The literature on the subject of the ductless glands has now assumed such proportions as to make it out of the question for any but special workers to keep pace with it, and information of much importance is steadily accumulating in this field. The present volume not only summarizes what is now known concerning the internal secretions, but also contains adequate discussions of the experimental work which has brought our knowledge to its present point. The author is well known as an investigator of these subjects and the book is therefore doubly valuable not only for the new matter which it contains, but also for the authoritative character of his judgment on the work of others. As is to be expected, the adrenals and the thyroids with the parathyroids receive the most space, and what is said concerning the latter organs will probably arouse much interest on account of the author's conservative attitude toward ascribing functions to them independent of those of the thyroid. In this connection he says, "From the standpoint of comparative anatomy, there are many reasons for believing that there is an intimate relation between the two structures, and the experimental evidence as to a supreme vital importance of the parathyroids as distinct from the thyroids is unconvincing." And further on, "It seems probable that we have to look upon thyroid and parathyroid as constituting one apparatus, and probably the pars intermedia of the pituitary body may have to be added as a third constituent of the apparatus." In view of the work of MacCallum, Voegtlin and others on the parathyroids in relation to the causation of tetany this seems an unnecessarily conservative opinion. Cushing's brilliant results in the treatment of acromegaly by operation on the pituitary also do not receive the recognition they deserve. On the whole, however, the work is remarkably comprehensive and will prove of the greatest value to research workers as well as to those who wish to keep informed as to progress in this very active department of physiology. For the purposes of the general reader especially the book is rather better adapted than the more discursive work of Biedl, which heretofore has been the only really comprehensive summary on the subject.

The Wellcome Photographic Exposure Record and Diary. London: Burroughs Wellcome & Co., 1913.

It is hardly necessary again to point out the many useful features embodied in the Wellcome Exposure Record. For the benefit of those who are not already familiar with it it may be stated that the little book contains blank pages for recording exposures, a diary for 1913, descriptions of all the usual photographic processes with tables and formulas, and the Wellcome exposure calculator. The latter has been improved so that it is now possible at one setting of the instrument to read directly the correct exposure for every lens opening.

The Wassermann Reaction—Its Technique and Practical Application in the Diagnosis of Syphilis. By John W. Marchildon, B.S., M.D., Assistant Professor of Bacteriology, St. Louis University Medical School. Price, $1.50. St. Louis: C. V. Mosby Company, 1912.

In this book the purpose has been to give the reader complete information that will enable him to get the material and to make the Wassermann reaction, providing he has a certain amount of laboratory training and skill. This purpose has been fairly well attained. The directions are exhaustively detailed though at times not as clear as might be desired. As the author states, it is desirable that the reaction be carried out only by trained laboratory workers in immunity and such workers would have but little use for a volume of this kind.

Diseases of the Liver, Gall-Bladder, and Bile-Ducts. By Humphry Davy Rolleston, M.A., M.D. (cantab.), F.R.C.P., Senior Physician, St. George's Hospital; Physician, Victoria Hospital for Children, Chelsea; formerly Fellow of St. John's College, Cambridge. Illustrated. Price, $9 net. London: Macmillan & Co., Ltd., 1912.

This handsome volume contains numerous papers on the subjects mentioned, which have appeared in various publications. Chief among these latter are the Encyclopædia Medica, the transactions of various medical societies, and medical journals. The author is well known as a scholarly writer and able editor; his name appears on the title-page of the new edition of Allbutt's System of Medicine, and he is a contributor to that peerless work as well as to Quain's Dictionary of Medicine. Those who are specially interested in the diseases of the liver will appreciate this volume; it is an admirable example of what such a monograph should be. The whole subject is discussed from the viewpoint of both the clinician and the pathologist; and at the same time, there is an ample bibliography. The work is no compilation, but is a well-planned and orderly treatise which represents a large amount of original work; the personal element is strong, but the views and labors of other workers are both recognized and acknowledged. Throughout, one feels in safe hands, and the value of the book is enhanced by the pleasure with which it can be read.

Life and Letters of Dr. William Beaumont. Including Hitherto Unpublished Data Concerning the Case of Alexis St. Martin. By Jesse S. Myer, A.B., M.D., Associate in Medicine in Washington University, St. Louis. With an Introduction by Sir William Osler, Bt., M.D., F.R.S., Regius Professor of Medicine in Oxford University, England. With Fifty-eight Illustrations. Price, $4. St. Louis: C. V. Mosby Company, 1912.

William Beaumont and Alexis St. Martin are names with which the medical student becomes acquainted very early in his career. Too often, it is to be feared, they remain mere names. Medical biography and medical history are, as a rule, sadly neglected; perhaps the overcrowded curriculum and irksome examinations are largely responsible for this state of affairs. But a similar excuse can hardly be found for the practitioner who, at least in the early years of his practice, has ample time for such reading, and now that we have this handsome volume by Dr. Myer no one need remain in ignorance of the life and work of our pioneer physiologist. The book is based on original letters and documents and represents a large amount of work on the part of its author. Throughout, this work has been done wisely; the author is in sympathy with his subject, and judiciously keeps himself in the background (a point too often ignored by biographers). This is in every way an important book, and the author deserves the thanks of American physicians for this well written biography of one of their number—a most patient and competent observer, whose life and work remain an exemplar and an inspiration.

Brewing. By A. Chaston Chapman, President of the Institute of Brewing, Fellow of the Institute of Chemistry of Great Britain and Ireland, Fellow of the Chemical Society. Price, $0.40 net. New York: G. P. Putnam's Sons, 1912.

Written with the purpose of acquainting the average layman with the principles underlying the various parts of the brewing process, this small volume is an attractive presentation of the subject. It contains a minimum of technicality and a large fund of information. It will prove interesting to any reader.

Serum Diagnosis of Syphilis and Luetin Reaction, together with the Butyric Acid Test for Syphilis. By Hideyo Noguchi, M.D., M.Sc., Associate Member of the Rockefeller Institute for Medical Research, New York. Third Edition. Price, $3. Philadelphia and London: J. B. Lippincott Company, 1912.

It is fortunate that the demand for this work and the size of the editions are such as to permit the issuing of frequent editions. The progress in this particular branch of medicine has been so rapid during the past three years that practically only those who are working in immunology have been able to keep pace with it. In this third edition Noguchi has announced his success in obtaining a pure culture of the *Treponema pallidum* and his application of emulsions of the organism to the diagnosis of syphilis by means of the luetin reaction. The luetin reaction is analogous to the tuberculin reaction in that it consists of the application to the skin of a preparation of dead organisms. It differs from the Wassermann reaction in that it is specific. The reports on this new test have so far been exceedingly favorable and it is likely to find high place among diagnostic methods. The rest of the book is practically unchanged from the second edition which appeared about a year and a half ago. The work is one of the most valuable which we have in this field and can be highly recommended.

Muscle Spasm and Degeneration in Intrathoracic Inflammations (Their importance as diagnostic aids and their influence in producing and altering the well established physical signs; also a consideration of their part in the causation of changes in the bony thorax) and Light Touch Palpation (The possibility and practicability of delimiting normal organs and diagnosticating diseased conditions within the chest and abdomen by very light touch). By Francis Marion Pottenger, A.M., M.D., LL.D., Medical Director of the Pottenger Sanatorium for Diseases of the Lungs and Throat, Monrovia, Cal. Sixteen Illustrations. Price, $2. St. Louis: C. V. Mosby Company, 1912.

In this extremely interesting and suggestive book the author points out the diagnostic significance of conditions of spasms and degeneration in the musculature of the neck and chest attending inflammatory intrathoracic lesions. These changes, which may be very slight or may be quite evident, are to be studied by minute inspection and by delicate palpation. By a still further refinement of the art of palpation Pottenger is able to outline organs such as the heart, liver, and spleen without the aid of percussion. The work deserves the careful study of every clinician, for undoubtedly the possibilities of inspection and palpation are seldom utilized as fully as they should be, even though it hardly seems likely that such unusual powers of observation and tactile sense as those possessed by the author will ever become common property.

Grundzüge für die Ernährung von Zuckerkranken. Nebst praktischen Anweisungen für die Diabetesküche. Von Prof. Dr. Albert Albu in Berlin. Price, 4 marks. Halle a. S.: Carl Marhold, 1912.

In most works on dietetics sections are devoted to the preparation of dishes for diabetics, and there are also several books on this subject alone, but in the opinion of the reviewer the present volume is the most satisfactory guide for the regulation of diabetic diets that has yet appeared. Albu states that physicians as a whole have not realized that in treating diabetes it is necessary to have a thorough acquaintance with culinary methods, and that while actual mastery of technical details is not required the medical attendant should at least theoretically be a good cook. Accordingly, we find that the larger part of the volume consists of recipes for a remarkably long list of dishes, together with general directions which should encourage attempts at the invention of new ones. Some of the ingredients naturally appear strange to American eyes and no doubt would prove still more so to American stomachs, but for the most part the dishes seem well adapted to tempt the appetites of every clime. The introductory chapter comprises an excellent discussion of the general principles on which the management of diabetic dietaries must be founded, in which emphasis is laid not only on testing the carbohydrate tolerance in the customary way, but also on the importance of determining the carbohydrate allowance on which the patient best utilizes the food given.

Papers on Psychoanalysis. By Ernest Jones, M.D. (London), M.R.C.P. (London); Associate Professor of Psychiatry, University of Toronto; Secretary of the American Psychoanalytic Association. Price $4 net. New York: William Wood & Company, 1913.

On the title page of this book there is a motto quoted from Freud: "Ein Nichtverstehen ist oft ein Nichtverstehenwollen (A failure to comprehend is often a want of desire to comprehend)." Freud and his exponents are perfectly aware of the credulity with which their novel teachings have been received in many quarters, nevertheless, their zeal in elucidating the principles of psychoanalysis has not abated. The present volume, which views this doctrine from many angles, comes from the pen of one of the foremost protagonists of the Freud theories. Whoever would profit by an enthusiastic and at the same time critical analysis of Freud's teachings will find this book one that admirably answers these purposes. The subject matter is not presented as in the ordinary textbook. It is embodied in a series of papers which were originally read before medical societies or published in various journals. These papers, although overlapping in some of their themes and illustrations, nevertheless present a most complete exposition of the theory and practice of psychoanalysis. The scope of this book can be best gauged by citing the various chapter headings. These are as follows: rationalization in everyday life; Freud's psychology; the psychopathology of everyday life; remarks on a case of complete autopsychic amnesia; a modern conception of the psychoneuroses; the relation between organic and functional diseases; simulated foolishness in hysteria; the pathology of morbid anxiety; psychoanalysis in psychotherapy; the psychoanalytic method of treatment; the word-association method in the treattment of psychoneuroses; the action of suggestion in psychotherapy; reflections on some criticisms of the psychoanalytic method of treatment; the therapeutic action of psychoanalysis; Freud's theory of dreams; the influence of dreams on waking life; the relations between dreams and psychoneurotic symptoms; a forgotten dream; note on the Œdipus saving phantasy; psychoanalysis and education; and the value of sublimating processes for education and reeducation. One of the most interesting of these chapters is that which deals with the psychopathology of daily life. The author discusses in a most entertaining manner the psychology of such common phenomena as forgetting, slips of the tongue, slips of the pen, misprints, false visual recognition, mislaying of objects, erroneously carried-out actions, and symptomatic acts. The rôle of the "complex," the subconscious motive that underlies many of the actions of an individual is discussed in its important bearings. The reader has no difficulty in grasping the principles of the Freudian psychology as set forth so lucidly in this work by one who has studied the subject carefully in its many aspects.

# Society Reports.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held February 24, 1913.*

The President, Dr. Brooks H. Wells, in the Chair.

**Report of the Committee of Fifteen upon Hospital and Dispensary Abuse.**—Dr. William S. Thomas, chairman of this committee, read this report, which was freely discussed by the members present. The results of the investigations of the dispensaries by members of the committee showed the following conditions respecting their compliance with the regulations of the State Board of Charities governing dispensary administration.

I. *Posting the Law.*—The requirement that the law be posted in the dispensary was generally complied with, but not always in a conspicuous manner. They recommended that these notices be printed in several languages and conspicuously posted.

II. *Registrar.*—The regulation governing registrars was as follows: "There shall be an officer to be known as 'The Registrar,' whose duties shall be to supervise the work of the dispensary, and either personally or by a competent deputy selected by him for that purpose, to make and preserve all records, receive all applicants, and see that all rules and regulations are enforced." They had found that all the dispensaries investigated were provided with registrars or deputies, as required.

III. *Admission of Applicants.*—The regulation governing the admission of applicants was as follows:

"Sec. 1. It shall be the duty of the registrar to examine all applicants to determine the question of their admission and the following rules shall guide his action: (*a*) All emergency cases shall be admitted and receive prompt treatment and care. (*b*) Every applicant who is, in the opinion of the registrar, poor and needy, shall be admitted. (*c*) Patients who are received in dispensaries connected with medical colleges, and whose cases are selected for clinical instruction may be admitted without examination as to their ability to pay for the services of a physician. (*d*) Every applicant, either personally, or by the parent or guardian of such applicant, whose personal appearance does not indicate that he is poor and needy shall be questioned by the registrar as to his ability to pay for medical or surgical relief, advice, or treatment, medicine, or apparatus, or either, in whole or in part, and if the registrar is still in doubt with regard thereto, the applicant shall be admitted to a first treatment on signing a card containing the 'representation' of statement of the applicant, but the registrar shall forthwith cause an investigation of his or her ability to pay either personally, or by parent or guardian; the results of such investigation, together with the representation card, shall be filed among the permanent records of the dispensary. Any such applicant who declines to sign the required 'representation' or statement shall be refused admission.

"Sec. 2. Such 'representation' or statement shall be in the following form:

Card of Admission on 'Representation' or Statement of Patient.

Name.....Date.....
Dr.....No. in family.....
Nationality.....Address.....
Occupation, Man.....Woman.....
Income.....Rent.....

This is my ..... application in this Dispensary in the year .....

I have been an applicant to no other Dispensary in the year ..... (or to the following Dispensaries: .....).

The foregoing statement is in all respects true.

Signature of applicant .....

Admitted..... Refused....."

*Comment.*—Inasmuch as this regulation left to the judgment of the registrar the admission or rejection of applicants, according to the personal appearance of the latter, it was essential that the registrar or his deputy be persons of considerable ability and discretion and in sympathy with the spirit of the law. In many instances it was found that the registrar was incompetent, or unable properly to comply with those provisions. The work of Miss Moore, the paid investigator of the 1,000 applicants, had incidentally strengthened the opinion of their committee in this matter. In order to correct this defect when existing in the administration of the dispensaries, the committee respectfully recommended the adoption of the following regulations: 1. That uniform records, preferably a card index system, be required in all institutions licensed by the State Board of Charities. 2. That said application card shall state the name, address, age, occupation, civil condition, personal income, and entire family income of the applicant who must sign his name thereto. 3. That each new applicant for free treatment be required to fill out such a blank before being assigned to any clinical department for treatment, emergency cases excepted. 4. Law fixing a penalty for false representation to be printed on back of patient's card.

The State Board's regulation was as follows: "The registrar shall issue to every applicant who is admitted for treatment a pass card on one side of which shall be printed the usual statement in regard to attendance upon the class to which he or she is assigned, and, on the other side, the card shall be in the following form:

"Penalty for False Representation. Section 296, Chapter 55, Consolidated Laws. Any person who obtained medical or surgical treatment on false representation, from any dispensary licensed under the provisions of this act shall be guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not less than two dollars and not more than two hundred and fifty dollars." (Imprisonment until fine was paid might be imposed. Criminal Code Pro., 718.)

*Comment.*—The Committee found that in some instances the penalty was not printed on the back of the admission cards and it therefore recommended that this regulation be enforced and that the law be printed in more than one language.

IV. *Enforcement of the Law Against False Representation.*—One weakness of the medical charity law lay in the fact that there was no present adequate means of its enforcement. The Committee recommended that the State Board of Charities be provided with sufficient funds to enable it to cause the enforcement of Section 296, Chapter 55, of the Consolidated Laws which concerned the obtaining of medical charity under false representation.

V. *Regarding Fees in Dispensary.*—The Committee felt that the custom of charging for drugs, appliances and other incidentals to treatment, and not charging anything for treatment, placed the burden of the charity of the dispensary exclusively on the medical profession, in those institutions where medical attendants were not paid salaries. The Committee believed that charitable institutions should dispense charity to the extent of their financial ability, and no more; and that they should not make money for the purpose of extending their work. Therefore, it recommended that there be no charge made for drugs in the dispensaries. The Committee believed that dispensaries should be maintained for the benefit of the poor only. In some institutions the Committee found that patients were charged to the extent of their ability to pay. The Committee recommended that such practice be discontinued by the dispensaries posing as charitable institutions and receiving benefactions as such from State or individual sources.

VI. *Location of Patients' Homes in Relation to the Dispensary.*—Their investigation had disclosed the fact that one of the most serious and, it would seem, the most easily remedied causes of dispensary abuse was the widespread custom of treating patients without regard to the location of residences in respect to the dispensary. Patients flocked to the city from the suburbs and distant regions. Others, dwelling here, roamed about the city from one dispensary to another seeking various diagnoses and trying to find treatment to their personal liking. The result was economic waste and detriment to the interest of the patient and of the medical profession alike. Nothing could be clearer than that the easiest way to reform this abuse would be through association of the dispensaries. They could unite in dividing the city into districts, and each institution could then refuse patients living outside its own sphere, referring them to the charitable institution of their own localities. In many other respects needed reform in dispensary management could best be effected by an association of dispensary authorities. The Committee recommended that the Society give its support to the Associated Out-Patient Clinics. The Committee did not feel at liberty to publish specific instances of the abuse of dispensaries on the part of their authorities, because its investigations were necessarily confined to a few institutions. Unless all the city's sixty-four dispensaries had been investigated it would be manifestly unfair to do so.

It was moved, seconded, and unanimously carried that the above report be accepted by the Society.

*Report of the Subcommittee on Lodge Practice.*—Dr. Samuel J. Kopetzky, Chairman of this Committee, said that this Committee which undertook an investigation into the subject of lodge practice submitted the following brief report: In the first place it was very difficult to get any exact figures. The only source of information available was a mutual friend through whom was reached an official of the Federation of Jewish Orders, and the Committee had every reason to believe the figures he gave were correct and represented the actual conditions regarding lodge practice among the Jewish elements of their population. Furthermore, they might be taken as a typical example of similar conditions among the Italian, German, Hungarian, Bohemian, and Swedish Christian organizations. The figures did not include insurance companies nor commercial corporations who employed doctors. In the State of New York there were 2,000 Jewish lodges. There were, besides these and not included in this report, small independent benevolent societies which employed physicians under contract in each and every one of the smaller towns of the State. Approximately one physician took a contract with three lodges on an average in the Greater City of New York. There were thus employed about 500 physicians under contract with Jewish lodges. No means of ascertaining the number of physicians in contract practice in the State were available. The 500 physicians above referred to receive pay at the rate of from one to two dollars a year per member of the lodge from which they received their contract. The average contract physician thus assumed the care of 500 or 600 members. In a certain number of contracts the physician must look after the wife and children of the members, the children numbering up to eight per member's family. Other lodges permitted an additional fee of one dollar per year for looking after the member's family. The men engaged in this form of practice averaged from ten to fifteen house calls a day, spread all over the Greater City of New York, and at their offices they saw from twenty to forty ambulatory cases. Briefly stated this was the condition prevailing in Greater New York among the Jewish orders, and when one took into consideration the large number of Italian orders, the commercial houses, the construction corporations, and the industrial insurance companies, it demonstrated that contract medical practice was engaged in by many more men than any of the medical societies had any definite knowledge of. The least number of these men engaged in this form of practice were members of the County Medical Society. They had no time for scientific work, no time for self-improvement, and were interested in nothing except to meet the demands of their contracts and make a sort of living. They could not do good work for their employers because they must contract to look after too great a number of persons at these small fees so as to make a living. The custom of fee splitting, to which most of these men resorted to make additional money, was in part the direct outgrowth of this form of contract practice. Averaging only from twenty-five to fifty cents a call, they thus gained a few dollars extra when they found they could call a surgeon or other specialist of their own selection. In the majority of instances, not being members of the organized societies, they were beyond reach of the societies' moral discipline. On the other hand, from personal interviews with some of the grand officers of these orders they learned that the employers of these physicians were aware of the poor character of the services they received and were apparently willing to meet the County Society, or any other regularly organized medical body, more than half way in an effort to effect mutual improvement. The question before them, therefore, became one of control first and correction of abuses second. Should the County Medical Society assume control of this form of practice? The Committee felt that since this form of practice was so extensive and the abuses attending it so great the County Society should further investigate and study this form of practice. There was no way in which it could be abolished. It was moved, seconded, and carried that the Committee be continued for another year.

There was no scientific session at this meeting.

---

**Immunization of Guinea Pigs with Nucleoproteins of Cholera Vibrios.**—V. de Bonis and P. Natale have found that the administration per os to guinea-pigs of the nucleoproteins of the cholera vibrio produces in these animals a reaction similar to that associated with the production of specific antibodies. Those animals that resist the toxic action of the nucleoproteins are also endowed with a considerable degree of immunity to cholera infections.—*La Riforma Medica.*

## MEDICAL ASSOCIATION OF THE GREATER CITY NEW YORK.

*Annual Meeting, Held January 20, 1913.*

The President, Dr. Reynold Webb Wilcox, in the Chair.

**Election of Officers.**—The following officers were elected *Recording Secretary*, Dr. P. Brynberg Porter; *Chairman for the Borough of Brooklyn*, Dr. Robert E. Goughlin; *Chairman for the Borough of Richmond*, Dr. William Bryan; *Member of the Council*, Dr. Louis Faugères Bishop.

**High-Tension Electricity as a Remedy with Presentation of Cases.**—Dr. J. Herman Branth, in this paper, said that he spoke as a general practitioner, whose knowledge of this and other subjects was founded not alone upon textbook information, but also upon personal experience. It was known by all who had studied electrical science that electricity, and principally high-tension electricity, is capable of urging metabolism into normal lines, and this would be the chief basis for the arguments presented. All electrical currents, however produced, which would leap through an air-space or "gap" were regarded as of high tension character, and some years ago he had demonstrated before the association that the extremely high tension current passes through every known insulator, either directly or by electric stress of opposite polarity; quantity, of course, being also considered a factor. On the basis that high tension electricity, in its passage, will affect and correct metabolic disorders in an organ, he had applied it with success to glandular tumors of the neck. It was true that the *x*-ray was also used in some instances, but greater reliance was placed on the high tension, high-frequency current, by the bi-polar method, a gentleman of 69 suffering sion current sent through a Leyden jar and on one or more spark gaps, and he had obtained a very high tension current by means of a Tesla coil step up transformer. One of the remarkable facts observed was that the application of a high tension, high frequency vacuum tube will give pain only when this is made to a diseased part; so that as a patient advanced toward normal conditions, the tolerance grew in the same degree. When the vacuum tube of a very high voltage apparatus was applied to the surface of the body there were produced redness and warmth, due to dilatation of the capillaries. More blood was attracted to the part, and this, according to Metchnikoff, meant increased phagocytosis. At all events, there was increased vitality of the tissue cells. Now, if this were a law, what should happen when the current was sent through an organ like the liver or kidney in a subnormal state? It would undoubtedly help or stimulate nature to overcome abnormal conditions if the vitality were not too exhausted to bar repair. So, too, in arteriosclerosis we should expect relief from a remedy acting in this manner. Acting on this hypothesis, he had treated with the high tension, high frequency current, by the bi-polar method, a gentleman of 69 suffering from general arteriosclerosis who a year ago last summer had to be sent home from the country on account of alarming cardiac symptoms. The result had been most gratifying. His general health was now good, his mind was bright, and he was engaged in literary work. Dr. Branth gave a word of warning here, however, in regard to the sending of the current through the heart. The electric force might disturb the rhythm of a weak heart, or might even stop it altogether. Tumors of the female breast, he went on to say, often yielded to this current in combination with the *x*-ray. It was well known that these growths generally, perhaps always, developed malignancy, but the knife was not always a sure remedy. Some two years ago a woman with a small tumor in the left mamma, who was being treated by him with this combined method, became dissatisfied because her case did not improve more rapidly and sought surgical intervention. This led by metastsis into general carcinoma, which terminated fatally last autumn. The treatment by the *x*-ray alone of tumors of the breast, or, in fact, of any deep-seated malignant tumor, had not in his hands been attended with success, though in superficial cancer its success was indisputable. The action of high frequency currents, he believed, was analogous to the methods of nature. In the case of an inflammatory lesion (a cut, a carbuncle, a pneumonia, or any other) nature always supplied fever heat in the process of repair, and a stream of electricity was also a stream of heat in such line as we chose through the body, while, in addition, the proper electrical current would promote in the body cells the throwing off of waste material and the taking in of nutriment. It was by no means his desire to replace internal or external medication by electricity; indeed, the two often admirably supplemented each other. As had been stated, vital metabolism was stimulated by electricity,

and, taking advantage of this fact, he had treated young girls with amenorrhea successfully, where iron medication alone had no effect whatever; the iron passing off in the blackened stools. As soon as static electricity was added to the treatment, however, the stools became lighter in color and the blood richer in hemoglobin. The same principle held good in the administration of arsenic, mercury, strychnine, and other drugs, and only half doses of these should be given when electricity was also employed. The speaker then illustrated the effect of very high tension electricity by a comparison with sounds and their perception. The human ear had a certain register of capacity, but above or below a definite range of sound vibrations we could not hear anything. The lowest note the ear could perceive was the sound of the 16-feet organ pipe: There was, however, an organ pipe 32 feet long which was inaudible if sounded alone; yet if this were sounded with the 16-feet pipe the latter's note was intensified, because its sound wave moved parallel with one-half the sound wave of the longer pipe. All kinds of electricity were the same kind of force; what variation existed was only of pressure (voltage) and quantity of flow (amperage). The voltage might be called the latitude of register. If we used the ordinary induced current with a Leyden jar of large size, the spark produced a painful sting, because it was within the nerves' register. If, however, we drove this same induced current through a step-up transformer until it got beyond the nerve register, we would have a current pressure which was quite bearable. This current reached an immense pressure (voltage), but, the output of the machine being always the same, we got a quantity (amperage) of inverse ratio to the voltage. Dr. Branth said he was perhaps the first to learn (many years ago) that by the interposition of a number of spark gaps an *x*-ray tube of low vacuum could be brought to act like a hard tube and attain greater penetration. Then it seemed to him that a force, like high tension electricity, moving at great velocity was difficult to divert from a direct line, and, if this were a fact, such currents would surely act upon internal organs lying on the line of the current. In high tension, high frequency electricity, as in the case of the *x*-ray, the interposition of multiple spark gaps would also induce penetration. High tension electricity undoubtedly had a field for remedial application, especially as we could apply it locally to a part (even to internal parts) which could not always be reached by internal medication.

The first case of which he gave a detailed report was a well-marked one of hepatic cirrhosis in a man of 59. The patient was emaciated and sallow, and apparently doomed to die. He had been tapped some seventeen times by his physician in Yonkers, 3½ gallons of fluid being removed every twelve days. The treatment instituted consisted of bitter tonics and the use of high tension bipolar electricity, and under this the accumulation of fluid in the abdominal cavity grew less and less rapid; so that tapping was required at increasingly longer intervals. The last tapping was done on November 5, 1911, and shortly after that he went to Florida, where he remained until April, 1912. He then returned to New York in excellent health, and Dr. Branth last saw him early in December, when he expressed the wish to be present at this meeting. Unfortunately, he contracted erysipelas the latter part of the month, and died from that disease on the 30th. His physician, Dr. Padgett, had informed Dr. Branth that not a vestige of the hepatic trouble was observable. Two other cases described were present in person.

Mrs. F., an Italian married woman, who came to America in 1910. Some time after her arrival her abdomen became enlarged. This was found to be due to fluid in the cavity, and it finally became necessary to tap her every seven or eight days, from 16 to 26 pints of fluid being removed each time. When she was referred to Dr. Branth he found the liver so much reduced in size that it could not be palpated even after the abdominal fluid had been evacuated. The same treatment was employed as in the preceding case, and with equally good results. The last electrical treatment was given on May 11, and since then she had remained well.

Mr. F., aged 17, a college student. Nine years ago he was operated on by Dr. Thorner for sarcoma of the left ilium, and subsequently he was treated by means of the *x*-ray by Dr. Branth, with the result of recovery in eighteen months. In February, 1912, a painful tumor appeared over the left lower ribs, a recurrence of sarcoma. He came to Dr. Branth on June 13, when it was found that he also had a lateral curvature of the spine, with rotation and deep depression of anterior and posterior of chest. He was given *x*-ray treatment, combined with the bi-polar high tension, high frequency current, and this afforded him relief much more quickly than the *x*-ray alone in the previous attack. Another and unexpected result was the reduction of the spinal curvature, with the removal of the chest depressions. It was unbelievable that the *x*-ray was a factor in this, but it might well be inferred that the high tension electric current, in passing through the subnormally nourished tissues, stimulated metabolism in them; and thus repair was inaugurated. This would seem like a profitable field for investigation. The patient was still under treatment, but the tumor was now very small and not very painful.

Dr. Frederick de Kraft said that the results which Dr. Branth had obtained by the utilization of high potential, high frequency currents in the cases presented were truly remarkable. In order to understand how he had achieved his success it might be well to consider briefly the method of producing these currents. If we attached a pair of small Leyden jars to each of the two prime conductors of a static machine and had the sliding rods slightly apart, the machine running at fair speed, we noted the rapid passage of sparks at the sliding rods. A pair of electrodes attached to the outer coatings and held the same length apart would also show a shower of sparks. Such an arrangement was shown by Dr. William J. Morton in March, 1881, under the name of static induced current. D'Arsonval interposed a stout copper spiral between the outer coatings, utilizing the same arrangement. Tesla made use of the inductive properties of a D'Arsonval spiral on a secondary spiral of greater length, interposing insulating material between the two for obtaining currents of high potential and high frequency, the D'Arsonval current being of low potential. That these currents can be made to penetrate the tissues could be clearly shown. A pair of electrodes attached to opposite sides of a D'Arsonval spiral were placed against the opposite sides of a potato, and a current of 1500 or more milliamperes was passed for two or three minutes; when steam would be seen to rise very quickly from the potato. On cutting through the potato we would find that the interior was cooked and mealy, while the skin had remained untouched. By the degree of cooking we could clearly trace the lines of current passage. Prolonged cooking would dry out the center in a straight line, while the rest of the potato was still moist and steaming. This principle could be utilized in practice; we could heat an organ to any desired degree. Dr. Branth had employed a Tesla coil energized by a Toepler-Noltz static machine of remarkable efficiency, and this apparatus he constructed himself. The current obtained from it was one of high potential and high frequency. By the use of a glass vacuum electrode attached to one end of the spiral and of a metal electrode attached to the other end he had secured a current of very deep penetrating and marked warming power. The first effect noted at the point of application of the glass vacuum electrode was pronounced anemia of the part, but this was quickly followed by an intense scarlatinaform erythma of long duration. If we applied a powerful irritant (such as this glass vacuum electrode afforded) to the skin we would find that the sensitiveness of the surface was much increased; but the feeling of pain soon diminished. The circulation in remoter organs was influenced, and by reflex action, vasomotor, sensory and motor nerves, glands, and involuntary muscular fiber were stimulated. Organs which were deeply seated were relieved of congestion by the hyperemia of the skin produced. Again, as the result of the heating effect occasioned by the molecular bombardment of this oscillatory current as it rushed through the tissues, we created centers of heat in every vital cell. As a further result we had an intensification of the circulation, arterial in kind. The arterioles became much dilated and the venous engorgement was relieved by a stimulation of the vasoconstrictor nerves, resulting in an attenuation of the abducent vein. The normal cellular activity was aroused as the result of the heightened nutrition made possible by the greatly increased flow of arterial blood, while, in consequence of the altered vascular supply the morbid interstitial tissue was subjected to an altered nutrition and disappeared. The pressure being relieved, especially in these hepatic cases, the flow of blood was guided into normal channels. It was thus that Dr. Branth had achieved his wonderful results, and he certainly deserved the commendation of all for having had the courage to apply these methods to such desperate cases, very few of which character had ever recovered under any plan of treatment.

Dr. Albert C. Geyser said that the cases presented by Dr. Branth spoke for themselves and therefore called for no discussion on his part. The technical portion of his paper, however, afforded much opportunity for elucidating remarks; though time would scarcely permit him to take up any other point than the title of the paper. Much had been said concerning high tension, high frequency, step-up transformers, dielectrics and high and low voltage; terms

which were very confusing to the average listener. The speaker then illustrated upon the blackboard the meaning of these various terms. If, he said, energy were applied to a piece of steel spring fastened to a holder, so as to bend it from its normal upright position to an angle of 45°, and keep it there, we would have, by the expenditure of energy produced in the spring, a form of kinetic or stored energy which, when released, would be turned into dynamic or moving energy. The effect of this dynamic energy would cause the spring to vibrate or oscillate from one side of its center or normal position to the other until, as the oscillations grew smaller and smaller, it would come to rest. The same amount of energy which was originally bestowed upon the spring was now returned to us in the form of oscillations. If this stored energy were released in a vacuum instead of the air, the vibrations would continue longer, on account of the lessened resistance. It was apparent that the farther the spring was originally forced from its normal position, the greater would be the tension or pressure. If a limiting buffer were placed upon either side of the spring, so that it could be bent from its path, say, one inch, we would have only as much tension or pressure as the bending of one inch would create. This, then, was high or low pressure tension in the spring, and we had an exact analogy in electricity. Whenever a current was induced through a non-conductor (dielectric) into some electrical capacity, stress, strain, pressure, tension or voltage was set up in that capacity. The capable voltage or tension depended upon the number of turns and other conditions in the secondary capacity, if that capacity happened to be a coil of wire.

If the primary current emanated from a static machine, the size or the diameter of the revolving plates decided the voltage. As the source, we might have either a transformer coil or static machine, and this source was analogous to the steel spring in which was stored kinetic energy. From it we had two conductors, and connected with each was an adjustable spark gap represented by the two buffers placed upon either side of the steel spring. Just as these buffers created the extent of the tension in the spring, so did the spark gap limit or control the tension or voltage in the electrical circuit. No more voltage could be created within this circuit than was necessary to break down the spark gap resistance. Just as soon as the voltage or tension had risen to the proper height to cross the intervening air gap, that moment a spark or series of sparks passed, and equalization or rest was restored in the tension of the electrical circuit. As we passed further down from the spark gap, the conductor came in contact with the inner lining of the condensers or Leyden jars. One conductor was the plus (+) or positive, and the other the minus (—) or negative pole. This inner side of the Leyden jar became an extension of the conductor, and in this way a capacity charged with the same kind of electricity as the conductor. The inner side of one of the two jars became charged with the positive kind, the other with the negative, while the glass wall acted as a non-conductor or dielectric. The same phenomenon occurred as before. By the process of induction, the same amount and the same stress, tension, or voltage was set up in the outer coating of the jar, but of opposite polarity. The inner positive jar caused the outer capacity to become negatively charged, and *vice versa*. If now a coil of wire consisting of a certain number of turns, in accordance with the rest of the apparatus, was connected to the outer coatings of the jars, we had constructed a D'Arsonval apparatus. From this spiral two conductors were led to the patient. Each time that the outer coatings were charged with the induced current they tended to discharge themselves—tended to equalize their stress or tension, with the same result as in the case of the spiral spring. Oscillations were thus set up which were large in amplitude at first, but gradually grew smaller until they subsided altogether. Then a new set of similar oscillations followed. It has been estimated by the experts of the wireless system that 200,000 of such discharges might take place per second, each discharge consisting of from 100 to 150 oscillations; so that there would be several million oscillations in a second. Hence the term high frequency.

Dr. William Stevens said he had had the opportunity of seeing the Italian patient at Dr. Branth's office. When she first came under Dr. Branth's care, November 14, 1911, she had been ill for a year, or more, and had been in the hands of a considerable number of physicians. There was apparently an obstruction of the portal circulation, and Dr. Branth suspected the presence of an inflammatory condition, due perhaps to colon bacillus or other microbic infection. There was on the abdomen a large, foul-smelling sore, which had been caused by canthridal blistering and also a large ventral hernia, the result of an exploratory laparotomy. The abdomen was enormously distended with fluid, and on its surface were black streaks. The prospect of relief, under ordinary methods of treatment, looked hopeless, and Dr. Branth, acting on the courage of his convictions, determined to employ the treatment described, believing it to be the only method which afforded any chance at all for the reestablishment of normal metabolism in the parts affected. The happy result all could judge of this evening.

Dr. Ernest F. Ruppe, the regular medical attendant of the patient with sarcoma, said he could fully substantiate all Dr. Branth's statements in regard to that case. Several surgeons had advised operation, but at the same time held out very little hope of a real cure. It then occurred to him to consult Dr. Branth, who had treated him successfully in the former attack, and the result was the most marvelous cure of osteosarcoma that he had ever witnessed. He could also testify to the remarkable disappearance of the lateral spinal curvature.

**Some Newer Methods of Treatment for Malignant Disease.**—Dr. William Seaman Bainbridge, who read this paper, made some introductory remarks in regard to the work of the Committee on Scientific Research of the New York Skin and Cancer Hospital in the testing of new methods, surgical and non-surgical, for the treatment of malignant disease. At the present time, he said that, with the assistance of his staff of research workers, he was conducting investigations along several different lines. No final conclusion could be announced concerning any of these investigations, and the present demonstration was merely a report of progress. With this in mind he spoke briefly of the work of the committee upon the following methods of treatment: 1. Electrical — (a) fulguration; (b) thermoradiotherapy; (c) electrocoagulation, thermopenetration, diathermy, etc. 2. Serological— (a) Vaughan cancer extract; (b) Skin and caner extract, etc. 3. Surgical — (a) ligation of pelvic arteries. Three patients, two of them women of advanced age, were presented who had been treated with remarkable results, by means of fulguration. Lantern-slide pictures were then shown of the de Keating Hart fulguration apparatus, of the Doyen electrocoagulation apparatus, and of a large number of patients before, during, and after treatment by different methods. A surgical procedure to which Dr. Bainbridge directed special attention was the method of the "starvation ligature" in the treatment of so-called inoperable cancer of the pelvis. He had resorted to this measure in some fifty cases of advanced irremovable cancer, sometimes in conjunction with the curettement of the diseased areas and sometimes in conjunction with one of the other methods of which he had spoken. The serological treatment, he went on to say, had received considerable attention on the part of the Research Staff of the Skin and Cancer Hospital, the results of which would be reported in due time. In closing he made an urgent plea for humanitarianism in the treatment of cases of so-called inoperable cancer, emphasizing the fact that in many instances ordinarily called inoperable much could still be done for the relief of suffering and the prolongation of life by the application, according to the circumstances of the case, of one or more of the various measures he had mentioned as now being employed at the Skin and Cancer Hospital.

Dr. Gordon K. Dickinson of Jersey City said that Dr. Bainridge had the aptitude and capacity for working out such problems as those presented this evening, and that the Skin and Cancer Hospital was well qualified to offer the facilities necessary for the purpose. The work done at that institution he had had the opportunity of seeing in a number of instances. The superficial cases were almost always successful, but in the deeper-seated ones the disease was apt to return and end fatally. In this connection he referred to a case of papilloma which had come under his observation, in which the patient was relieved for a time, but eventually died. As to the treatment described there was something more in electricity and this type of current which we did not yet understand. He could but feel, however, that a good deal of the success which had attended the fulguration method was due to the operative procedures before its application.

Dr. Herman J. Boldt said he was simply astonished at the results accomplished, as portrayed upon the screen. Dr. Bainbridge, he thought, was to be particularly congratulated upon the manner in which he had combined these special forms of treatment with surgery. In the treatment of cancer we might never, perhaps, be able to decide upon any one specific, but it had been shown that we now had methods for curing a large proportion of cases, and in the others for relieving the pain and prolonging life. Personally, he believed that in serology there would be found a wiser field of usefulness than in any other direction. In the cases Dr. Bainbridge had described

and shown, however, he was convinced that no other treatment than that employed could have given such successful results.

Dr. Edward M. Foote said that the results shown this evening illustrated strikingly the advances which had been made in the treatment of malignant disease. Electricity, chemistry, and serology were now called into requisition, in addition to surgery, and they all had their advantages. We had reason to hope for still further results in the future, and as time went on we would find out what measures were best.

Dr. Worthington Seaton Russell said that in the case of Hodgkin's disease, which had been shown upon the screen, the patient had come to the Skin and Cancer Hospital from another hospital, where he had been told that his case was hopeless. There were immense masses on both sides of the neck, and not only were the cervical glands enlarged, but also those of the axillæ and other parts. Up to the present he had received thirteen treatments. At first the treatments caused some systemic reaction, but later on there was no reaction, and he was now receiving massive doses. The various glands had become much reduced in size, and in some of them the enlargement had entirely disappeared. The man was a florist, and was able to work regularly at his business. What the ultimate outcome might be no one could say, but, at all events, the treatment would undoubtedly prolong the patient's life. The case of tumor in the lungs, *x*-ray pictures of which had been shown, had received eleven treatments. It had been pronounced quite hopeless in a number of hopitals; yet this patient was now out every day and was able to do a certain amount of work. It was scarcely to be expected that he would be cured of his tumor, but his condition had certainly been greatly relieved. Very careful statistics of all these cases were being kept.

Dr. William Benham Snow said that the hot spark, as delivered from a high frequency apparatus, was not fulguration proper, but what might be, and was correctly, called destructive fulguration; while the desiccation method of Clark dried out the tissues, and thus destroyed them. The long, cooled spark of de Keating Hart did not destroy tissue, but acted as a stimulant, which overstimulated all of the tissues to the extent that the cancer cells perished. The reparative process after its application was slow. During this there was a profuse discharge of serum, a lymphorrhea, in the course of which the cancer cells perished. As to Hodgkin's disease, he had seen a case, treated by Dr. Herman Grad, in which there was extensive enlargement of many of the glands in the neck, axilla, and groin. Under *x*-ray treatment these all disappeared, but at the same time the red blood cells became more and more reduced until death ensued. In the case shown on the screen and further described by Dr. Russell, he would like to know whether there had been any change of this kind observed in the blood count. He was much pleased to see the tendency at the present time to the joint use of surgery and the *x*-ray and other electrical measures, a matter which he had advocated for years. In regard to the removal of lymphatic glands, he thought that in all cases only the enlarged glands should be removed, because these glands were defenses retarding extension in case of recurrence. The removal of the glands of the axilla and beneath the pectoral muscle was often too radical when the *x*-ray or fulguration could be used in addition to surgery. He hoped that the method described by Dr. Bainbridge would lead to the conclusion that it was not advisable to remove other than the diseased glands.

## NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

*Stated Meeting, Held January 21, 1913.*

Dr. Linsey R. Williams in the Chair.

**Demonstration of Bloodless Phlebotomy (Phlebostasis).**—Dr. S. Lilienstein of Bad Nauheim presented and described an instrument which had proved a valuable adjunct in the treatment of weakened heart action in cases of decompensation. Reduced to its simplest terms, this instrument consisted of two hollow cuffs connected with a manometer and a rubber bulb. The cuff was placed around each upper arm. Air was then pumped into the cuffs through the rubber bulb and at the same time the pulse was controlled. A pressure of 80 to 100 mm. mercury was usually sufficient. At this pressure the pulse was not entirely obliterated: only the venous flow from the arm was retarded, with the result that a peripheral congestion of blood ensued. In patients suffering from cardiac dyspnea, dull feeling in the head, feeling of oppression, etc., a marked improvement was felt after this treatment. During the past two years this instrument had been used over five hundred times with the usual good effects described. The degree of relief obtained varied with the nature of the heart lesion and the amount of decompensation. The speaker cited a number of illustrative cases in which this treatment had been followed by symptomatic relief lasting several hours. The principle of the method was that venous stasis in the periphery produced unburdening of the heart. Phlebostasis, as Dr. Lilienstein had designated this method, was almost equivalent to venesection, with the difference that there was no loss of blood, and so one was justified in calling it bloodless phlebotomy. This method of treatment would not revolutionize the present therapy of the heart nor could one do more with it than with the standard chemical heart tonics, digitalis, strophanthus, and their derivatives, or by physical therapeutic means. But all those who were called upon to treat continually so many cases of objective and subjective disturbances of the heart had experienced the gratefulness of chronically ill patients for every new effectual means of relief. This instrument gave a rapid relief of subjective symptoms.

**Demonstration of the New Electrocardiophone.**—Dr. S. Lilienstein exhibited and described this instrument. He did not go into the technical detail of construction, but stated that the apparatus was a kind of heart telephone and enabled the surgeon to control heart action during narcosis. It permitted the operator to have both hands free while listening to the heart. Furthermore it permitted the heart to be watched for long periods of time from a distance—during balneological procedures, packings, vapor baths, etc.—an observation which was valuable in sanatoria, bathing establishments, and similar institutions. At Nauheim he had an electrical arrangement leading from the different bathing compartments to a side room where he watched the cardiac cases. In his own home he had an electrical system connecting one room with another which permitted him to observe patients from another room. Patients were frequently very nervous and their heart action became aggravated under direct examination. The same principle that governed this simple apparatus had been applied to a larger one which served to demonstrate heart sounds and murmurs to a large audience. By transforming the electric current, the heart sounds and murmurs taken up by the microphone might be heard by from ten to twenty persons. He had named this instrument the cardiophone and it enabled him to register graphically the heart sounds and murmurs, as could be seen by the curves exhibited. An additional galvanometer was necessary for recording the curves. It was very instructive to have the heart sounds and murmurs registered by curves, as these curves demonstrated variations corresponding to definite pathological states whose significance had not yet been recognized.

Dr. Arthur D. Hirshfelder of Baltimore, Md., presented some photographs and lantern slides of the electrocardiophone and also some tracings that had been made of complete heart block. The auricular sounds were audible and the successive systoles enabled one to make a diagnosis clinically of complete heart block. The ventricular rhythm was regular. They had found this instrument very useful in teaching students; they first listened to the heart in the ordinary way and their findings were then compared with the tracings obtained by the use of the electrocardiophone; in this way it was hoped that they could improve their acumen in accuracy of diagnosis.
